Abstract

The study of photoproduction reactions has gained a unique opportunity with the HERA data. The high center of mass energy allows to carry out quantitative tests of QCD, to explore the substructure of both the photon and the proton and to shed new light on soft and diffractive processes. In this report we review the HERA results, comparing them with the reach of fixed target photoproduction experiments and complementary measurements from e^+e^- and hadron colliders.

1 Introduction

High energy photoproduction processes occur with high cross sections at the HERA ep collider ($\sqrt{s} = 300$ GeV), due to the large flux of quasi real photons from the electron beam. The obtained γp center of mass energies are up to ten times the values reached by fixed target experiments. The integrated luminosity achieved in the first years of HERA running has produced a great yield of physics output. With increasing luminosity the improvement of some of these measurements relies on a quite precise knowledge of the responses of the various detectors. The HERA results have also triggered a huge amount of theoretical activity.

The field covered by photoproduction at HERA has several connections with physics at e^+e^- and hadron colliders. The photon structure is probed in a complementary way with respect to the deep inelastic $e\gamma$ scattering at e^+e^- colliders. Moreover most of the photoproduction processes are seen to resemble hadron-hadron processes and can be described in a similar framework. It is non-trivial to say that we are testing our understanding of the high energy scattering with different beam particles and the universality of the underlying picture.

We review here the photoproduction results from HERA. In section 2 an introduction is given on the concept of the photon as a hadron, the measurements of its hadronic structure in the $e\gamma$ deep inelastic scattering, the definition of parton distributions for the photon and the most used sets of parametrizations. The basic characteristics of HERA, its kinematics and the experimental procedure to select photoproduction events are described in section 3 and a brief description of the ZEUS and H1 detectors is given in section 4. The physics topics are then grouped in the following way: soft physics is dealt with in section 5, where the measurement of the total γp cross section and its decomposition in the different diffractive and non diffractive processes are described and in section 6, where the elastic vector meson production is described; hard photoproduction is then the subject of section 7, where the emphasis is on both tests of the QCD dynamics and on the determination of the photon and the proton structure from measurements of inclusive particle, jets, open charm and inelastic J/ψ production; section 8 is devoted to hard diffraction, where both photon dissociation with the appearance of jets or heavy flavours and colour singlet exchange are described. Section 9 concludes with some remarks about the future prospects.

2 Resolved photon and photon structure functions

In the Standard Model the photon is the gauge particle exchanged in electromagnetic interactions. It is elementary and its fundamental interactions occur with the charged leptons and quarks. On the other hand hadrons are composite objects, bound states of quarks and gluons, and have a size of the order of 1 fm (10^{-13} cm). Despite this classification the photon can also behave like a hadron. The dual nature of the photon

was first observed in fixed target photoproduction experiments using real photon beams [1]. These experiments have covered center of mass energies from 1 to about 20 GeV. The hadronic behaviour of the photon has been interpreted in the Vector Dominance Model (VDM) [2]. It describes the photon-nucleon interaction as a two stage phenomenon: firstly the photon fluctuates into a vector meson state with the same quantum numbers $J^{PC} = 1^{--}$ (ρ^0, ω, ϕ), then a normal hadronic interaction takes place between the nucleon and the vector meson. The total cross section is written as:

$$\sigma(\gamma N \rightarrow X) = \sum_{V=\rho,\omega,\phi} \frac{\pi\alpha}{\gamma_V^2} \sigma(VN \rightarrow X) \quad (1)$$

where γ_V is the photon-meson coupling, which can be measured from electromagnetic decay rates like $V \rightarrow e^+e^-$. Photoproduction cross sections are suppressed by the QED coupling α in comparison to purely hadronic ones, but the characteristics of the final state are found to be the same as e.g. πN interactions.

The bulk of hadronic interactions are soft processes involving low momentum transfers. However at high enough energies hard interactions can occur, their signature being the production of high p_T particles or jets. In Leading Order of QCD (LO) the strong coupling constant α_s has the expression:

$$\alpha_s(\mu^2) = \frac{12\pi}{(33 - 2n_f) \ln\left(\frac{\mu^2}{\Lambda^2}\right)} \quad (2)$$

with n_f the number of active flavours. Whenever the characteristic energy scale μ of the interaction, like the p_T of the produced jet, is much higher than the QCD scale Λ (≈ 0.2 GeV), α_s is small enough to apply perturbation theory.

In hard γN interactions the photon can behave as a pointlike particle in the so-called *direct* photon processes or it can act as a source of partons, which then scatter against partons in the nucleon, in the *resolved* photon processes. Resolved interactions stem from the photon fluctuation to a $q\bar{q}$ state (or a more complex partonic state). Depending on the relative transverse momentum between q and $\bar{q}$, this may be a bound state like in the VDM (*hadronic* component) or a perturbative calculable state (*anomalous* component). Both are embedded in the definition of the photon structure functions.

The apparent hadronic structure of the photon can be studied in $e\gamma$ deep inelastic scattering at e^+e^- colliders. This proceeds through the exchange of two photons, one highly virtual (probe) and the other almost real (target), as in Fig. 1. Experimentally one electron is detected at a large angle with respect to its initial direction, and its energy E_{tag} and polar angle θ_{tag} are measured; the other electron is required to scatter at small angle, generally by an antitagging condition, and it is thus lost into the beam pipe (single tag). Without tagging the electron scattered at low angle, the energy and small virtuality of the target photon are undetermined. It is then necessary to measure the hadronic invariant mass W_{had} . The following kinematic variables are defined, with reference to Fig. 1 (k is the four-momentum of the incoming electron):

$$\begin{aligned}
Q^2 &= -q^2 = 2E_{beam}E_{tag}(1 - \cos\theta_{tag}) \\
W_{had}^2 &= (q + p)^2 \\
x &= \frac{Q^2}{2p \cdot q} = \frac{Q^2}{Q^2 + W_{had}^2} \\
y &= \frac{p \cdot q}{p \cdot k} = 1 - \frac{E_{tag}}{E_{beam}} \cos^2 \frac{\theta_{tag}}{2}
\end{aligned} \tag{3}$$

The reaction $e^+e^- \rightarrow e^+e^-hadrons$ can be regarded as $e \gamma \rightarrow e hadrons$ factorizing the flux of quasi-real photons, i.e. the lower vertex in Fig. 1. This is achieved in the Weiszäcker-Williams approximation [3] or better in the Equivalent Photon Approximation [4]. Naming z the energy fraction carried by the quasi-real photon, the differential cross section versus z , integrated over the photon virtuality P^2 between the limits P_{min}^2 and P_{max}^2 , is:

$$\frac{d\sigma}{dz}(ee \rightarrow eeX) = f_{\gamma/e}(z) \sigma(e\gamma \rightarrow eX) \tag{4}$$

with the photon flux $f_{\gamma/e}$ given by:

$$f_{\gamma/e}(z) = \frac{\alpha}{2\pi} \left[\frac{1 + (1 - z)^2}{z} \ln \frac{P_{max}^2}{P_{min}^2} - 2m_e^2 z \left(\frac{1}{P_{min}^2} - \frac{1}{P_{max}^2} \right) \right] \tag{5}$$

Here P_{min}^2 is the kinematic limit:

$$P_{min}^2 = \frac{m_e^2 z^2}{1 - z} \tag{6}$$

while P_{max}^2 corresponds to the maximum scattering angle θ_{max} for the electron not to be detected (typically $\theta_{max} \sim 30$ mrad):

$$P_{max}^2 = (1 - z)E_{beam}^2 \theta_{max}^2 \tag{7}$$

The level of accuracy of the Equivalent Photon Approximation goes from few per cent to about 10 %, depending on the P^2 range of integration.

The cross section for the deep inelastic $e\gamma$ scattering is written in complete analogy to the electron-nucleon DIS, introducing the two photon structure functions F_2^γ and F_L^γ :

$$\frac{d\sigma(e\gamma \rightarrow eX)}{dE_{tag} d\cos\theta_{tag}} = \frac{4\pi\alpha^2 E_{tag}}{Q^4 y} \left\{ \left[1 + (1 - y)^2 \right] F_2^\gamma(x, Q^2) - y^2 F_L^\gamma(x, Q^2) \right\} \tag{8}$$

In the usual experimental conditions y^2 is rather small and F_L^γ can be neglected. The cross section measurements thus correspond to determinations of the F_2^γ structure function.

The most striking feature of F_2^γ is that in the region of asymptotically high Q^2 it is completely calculable by perturbative QCD (at large x). This has to be contrasted with the nucleon structure functions, for which QCD predicts for example the Q^2 evolution but not the absolute normalization at any Q^2 value.

The lowest order contribution to F_2^γ is given by the Quark-Parton Model diagram shown in Fig. 2 (plus its crossed one), which is purely electromagnetic. It gives [5]:

$$F_2^\gamma(x, Q^2) = \frac{3\alpha}{2\pi} \sum_{q=1}^{2n_f} e_q^4 x \left\{ [x^2 + (1-x)^2] \ln \frac{Q^2 (1-x)}{m_q^2 x} + 8x(1-x) - 1 \right\} \quad (9)$$

where the sum runs over all quark and antiquark flavours q . The charge (in units of the proton charge) and mass are given by e_q and m_q . This expression depends on the quark masses and roughly describes experimental data using constituent masses of few hundred MeV. However it shows some important qualitative features. Comparing it to the known behaviour of the F_2^N nucleon structure function two major differences appear:

- There is no scale invariance holding for F_2^γ even in the Parton Model. For nucleons the scaling violations result from gluon radiation and have opposite signs in different x ranges: with increasing Q^2 F_2^N increases at low x while it decreases at high x . Instead F_2^γ grows at all the x values with increasing Q^2 .
- F_2^γ is large at high x , while counting rules predict for the nucleon a vanishing F_2^N for $x \rightarrow 1$.

The different behaviour of photon and nucleon structure functions originates from the pointlike coupling of the photon to quark-antiquark pairs $\gamma \rightarrow q\bar{q}$: this coupling is what endows the photon with a hadronic structure. Perturbative QCD can be applied on top of the Parton Model and resummations have been performed for F_2^γ both in leading [6] and next-to-leading (NLO) order [7] of QCD for large x and asymptotically high Q^2 . The result reads as:

$$F_2^\gamma(x, Q^2) = \alpha \left[\frac{a(x)}{\alpha_s(Q^2)} + b(x) \right] \quad (10)$$

with a and b calculable functions of x but diverging for $x \rightarrow 0$. The first term is the LO result, the second its NLO correction. The absolute normalization of F_2^γ would then be a direct measurement of $\alpha_s(Q^2)$, or equivalently of the QCD scale Λ . This result accounts for only pointlike couplings and is valid at high Q^2 where the incalculable hadronic component of the photon is not important. Unfortunately this regime is not experimentally reachable at present and foreseeable future accelerators. Non-perturbative contributions due to the formation of bound states after the $\gamma \rightarrow q\bar{q}$ splitting cannot be neglected.

The successful approach to F_2^γ , firstly suggested by Glück and Reya [8], requires the introduction of boundary conditions, which have to take inputs from experimental data at some arbitrary scale Q_0^2 already in the domain of perturbative QCD. At the scale Q_0^2 both perturbative and non-perturbative contributions are buried together. From the boundary conditions the evolution with Q^2 is then described by perturbative QCD, most practically with generalized DGLAP equations [9]. At the starting scale Q_0^2 parton densities are defined with a quark-antiquark component $q^\gamma(x, Q_0^2) = \bar{q}^\gamma(x, Q_0^2)$ and a gluon component $g^\gamma(x, Q_0^2)$. The evolution equations for the photon parton densities differ from those of

the nucleon due to the anomalous coupling $\gamma \rightarrow q\bar{q}$. Its splitting function is given by the coefficient of the leading logarithmic term in (9):

$$k_i(x) = 3e_i^2 [x^2 + (1-x)^2] \quad (11)$$

The anomalous coupling introduces an inhomogeneity in the evolution equations, which are written in the form:

$$\begin{aligned} \frac{dq_i^\gamma(x, t)}{dt} &= \frac{\alpha_{em}}{2\pi} k_i(x) + \frac{\alpha_s(t)}{2\pi} \int_x^1 \frac{dx'}{x'} \left[P_{qq}\left(\frac{x}{x'}\right) q_i^\gamma(x', t) + P_{qg}\left(\frac{x}{x'}\right) g^\gamma(x', t) \right] \\ \frac{dg^\gamma(x, t)}{dt} &= \frac{\alpha_s(t)}{2\pi} \int_x^1 \frac{dx'}{x'} \left[\sum_{j=1}^{2n_f} P_{gq}\left(\frac{x}{x'}\right) q_j^\gamma(x', t) + P_{gg}\left(\frac{x}{x'}\right) g^\gamma(x', t) \right] \end{aligned} \quad (12)$$

Here $t = \ln\left(\frac{Q^2}{\Lambda^2}\right)$, q_i^γ and g^γ are the quark (antiquark) and gluon density in the photon and P_{ij} ($i, j = q, g$) the ordinary splitting functions. Equations (12) hold in this form at both LO [6, 10] and NLO [11, 12, 13], provided the right one or two loop splitting functions and coupling constant α_s are used. Recently a full NLO calculation of the heavy quark contribution to the photon structure functions has been carried out [14].

A peculiar characteristic of the photon structure is that there is no momentum sum rule constraining the photon parton distributions. In contrast in the nucleon case the early DIS data showed that gluons should carry about half of the nucleon momentum, thus fixing the size of $g^N(x, Q_0^2)$. The reason is that in the quantum decomposition of the real photon the hadronic states and thus the parton densities are of order α_{em} , while the bare photon state is of zeroth order. Thus any variation, even large, in the parton densities can be reabsorbed in a renormalization of the bare photon wavefunction [15, 16].

Quark and antiquark distributions are however constrained by the measurements of F_2^γ , since in LO:

$$F_2^\gamma(x, Q^2) = \sum_{i=1}^{n_f} e_i^2 [xq_i^\gamma(x, Q^2) + x\bar{q}_i^\gamma(x, Q^2)] \quad (13)$$

The first data on F_2^γ came from experiments at the e^+e^- colliders PETRA and PEP (for a review see [17]). Most of the available photon parton distributions have been parametrized from those data. Later results have come from the TOPAZ [18] and AMY [19] experiments at TRISTAN and from the OPAL [20, 21] and DELPHI [22] experiments at LEP. They are shown in Fig. 3 compared to LO parametrizations obtained from previous data. Most of the data points suffer from quite large errors. One of the limitations are the low statistics in comparison with similar measurements of the nucleon structure functions. The reason is that the two-photon exchange implies a cross-section of order α_{em}^4 instead of α_{em}^2 as for lepton-nucleon DIS. Another important contribution to the experimental errors is of a systematic nature. As we said, the measurement of x requires that of W_{had} . Due to the limited acceptance of the detectors, particularly around the

beam pipe, one is not sensitive to the whole hadronic final state. To correct for detector effects a model of the hadronic final state is necessary and this is usually done with the help of Monte Carlo generators. Unfortunately the unfolding of the true W_{had} from the measured one is strongly dependent on the different models, especially at low x . The expected accuracy of the measurements which can be done at LEP2 in an enlarged kinematic domain is certainly very desirable [23]. The knowledge of the photon structure is of utmost importance at LEP2 for the research of new physics, given that the $\gamma\gamma$ processes are an important source of background.

The logarithmic increase of F_2^γ with Q^2 , predicted by (9), is clearly established from experimental data in Fig. 4, where F_2^γ is averaged in the large- x region $0.3 < x < 0.8$. This behaviour is a proof of the anomalous component of the photon. To account for the normalization a non-perturbative VDM component is also needed, like in the FKP model [24] shown by the curves in the figure.

Most of the current sets of parton distributions of the photon follow the approach of evolution equations. A deeper description can be found in [25]. The Drees and Grassie parametrization (DG) [26] was obtained by LO evolution equations starting from input parton distributions at $Q_0^2 = 1 \text{ GeV}^2$, to fit only one data point at that time available at $Q^2 = 5.9 \text{ GeV}^2$. Its input consists of three quark flavours with densities assumed proportional to the squared quark charges and flavour thresholds for charm and beauty crossed through the Q^2 evolution. The input gluon is generated radiatively and does not enter in the fit.

A similar strategy was used in the parametrizations by Levy, Abramowicz and Charchula (LAC) [27], which were based on the world data set available in 1991. However they included in the fit the gluon distribution at the starting scale, demonstrating that data on F_2^γ do not constrain it significantly. This is connected with the lack of a momentum sum rule for the parton distributions in the photon. Among the LAC sets, LAC1 and LAC2 have a very soft gluon distribution, rising steeply at low x , while LAC3 has a very hard distribution, with a maximum at $x \sim 0.9$. The LAC parametrizations are LO and use four massless quark flavours. LAC3 has already been excluded by data on jet production in γp and $\gamma\gamma$ scattering.

The WHIT parametrizations [28] (after Watanabe, Hagiwara, Izubuchi and Tanaka) follow a similar approach as LAC, but treating correctly the charm threshold. This is more important than in the nucleon case, because the photon can easily develop a charm content through the anomalous splitting $\gamma \rightarrow c\bar{c}$. Six sets have been provided, each one with a different assumption on the shape of the gluon distribution. The total momentum carried by gluons is however fixed at about half the momentum carried by quarks (at $Q_0^2 = 4 \text{ GeV}^2$) in WHIT 1,2,3, while gluons and quarks carry about the same momentum fraction in WHIT 4,5,6.

The Gordon-Storow parametrizations (GS) [29] exist at both LO and NLO. Their first version starts from a scale $Q_0^2 = 5.3 \text{ GeV}^2$ with a VDM ansatz modified by the addition

of a pointlike term:

$$(q^\gamma, g^\gamma)(Q_0^2) = k \frac{4\pi\alpha}{f_\rho^2} (q^{\pi^0}, g^{\pi^0})(Q_0^2) + (q^{QPM}, g^{QPM})(Q_0^2) \quad (14)$$

Here the structure of the vector meson is assumed equal to the pion structure. The free parameters are the momentum fractions carried by gluons and sea quarks in the pion, the constant k and the light quark masses from the QPM term. In the GS2 distribution $g^\gamma(Q_0^2)$ comes entirely from the first term, while in GS1 the second term also contributes through radiation from the pointlike quark component. Recently these distributions have been updated [30] by lowering their starting scale to 3 GeV², including all available data on F_2^γ and constraining the gluon from jet production data at TRISTAN.

The GRV parametrizations (after Glück, Reya and Vogt) [31] exist both in LO and NLO and are built at a very low starting scale: $Q_0^2 = 0.25$ GeV² (LO), 0.3 GeV² (NLO). Such a low value is considered the minimum for the applicability of perturbative QCD. The authors apply the idea of *dynamically* generated parton distributions, which they had previously used to describe the nucleon and pion structure [32]. The ansatz for the nucleon was originally to have only valence quarks at the initial Q_0^2 scale. It was then modified introducing valence-like distributions of gluons and sea quarks. For the pion no sea quarks are needed at the starting scale Q_0^2 but a valence-like gluon density, proportional to the valence quark density. The GRV approach has attained considerable success with HERA data on the proton F_2 structure function [33, 34], although it is not obvious that perturbative QCD implemented in DGLAP equations works already at $Q^2 < 1$ GeV². The GRV parametrizations for the photon start from a VDM input:

$$(q^\gamma, g^\gamma)(Q_0^2) = k \frac{4\pi\alpha}{f_\rho^2} (q^{\pi^0}, g^{\pi^0})(Q_0^2) \quad (15)$$

where only a normalization factor k ($1 \leq k \leq 2$) remains free, accounting for $\rho/\omega/\phi$ mixing. In this way the gluon distribution at the scale Q_0^2 is constrained to be equal to that of the pion.

The AFG parametrization (after Aurenche, Fontannaz and Guillet) [35] is built in NLO and, like GRV, starts from a low scale $Q_0^2 = 0.25$ GeV² assuming a VDM ansatz. However a coherent sum of ρ , ω , ϕ is supposed. Pion distributions are taken from [36]. The authors choose the $\overline{MS}$ regularization scheme pointing out that the DIS_γ scheme adopted by GRV is more stable but includes process dependent terms in the parton distributions.

Schuler-Sjöstrand parametrizations [37] are quite recent and follow a similar approach as GRV and AFG. They exist only in LO. Different sets are provided, including parton distributions for the virtual photon.

Summarizing, the VDM ansatz allows one to constrain the gluon distribution in the photon, otherwise free due to the lack of a momentum sum rule. Unfortunately with typical starting scales $Q_0^2 > 1$ GeV² a pure VDM input is not able to reproduce data at higher Q^2 . The various parametrizations solve the problem by adopting one of these two approaches:

- starting from a very low scale Q_0^2 with a pure VDM input, in a region where perturbative QCD may be doubted;
- keeping the scale at $Q_0^2 > 1 \text{ GeV}^2$ and using a more complex input with the addition of a pointlike component given by the Quark-Parton Model or simply guessed.

A comparison between the quark distributions from different sets is shown in Fig. 5. There is reasonable agreement between them in the region $0.05 < x < 0.8$, where F_2^γ data exist. Instead large differences appear at high x , for example comparing GS and GRV. The striking difference between the quark distribution in LO and NLO is characteristic of the $\overline{MS}$ scheme, and this has been discussed in [15]. It does not affect the final predictions on observable quantities like F_2^γ . It can however be avoided using the DIS_γ scheme which is adopted by the GRV parametrizations [13].

Large differences between the parametrizations also occur at low x . This is clearly visible in Fig. 6, where different LO gluon distributions are compared. The LAC sets are much steeper at low x than the others, demonstrating that the $e\gamma$ DIS data do not constrain the gluonic component of the photon. At NLO the similarity of the curves is due to the similarity of the models, it is not borne out by data.

The first experimental constraints on the gluon density in the photon have come from e^+e^- experiments at TRISTAN ($\sqrt{s} = 58 \text{ GeV}$) from the study of $\gamma\gamma$ interactions, with both photons almost real. Here jet production occurs in LO through the Quark-Parton Model process as in Fig. 7/a, or through *single*- or *double-resolved* processes as in Fig. 7/b-c. The three kinds of processes are all of the same order in the coupling constants since the photon parton distributions are $O(\alpha_{em}/\alpha_s)$. The first experimental evidence for a non zero gluon content came from AMY [38]. Single jet and dijet inclusive cross sections have then been measured by both TOPAZ [39] and AMY [40]. The results of TOPAZ compared to theoretical predictions are shown in Fig. 8. The need for the hadronic component of the photon is evident when comparing data to the expected cross section for direct photon only. Moreover it is clear that there is a need for a gluon component in the photon. These data also rule out the LAC3 parametrization which would predict a far too high cross section.

3 HERA as a γp collider

The HERA storage ring at DESY (Hamburg, Germany) is the first electron-proton collider ever built. Two different magnetic systems, respectively superconducting for protons and conventional for electrons, drive the beams in separate rings along a circumference of 6.3 Km. The design energies are $E_e = 30 \text{ GeV}$, $E_p = 820 \text{ GeV}$, giving a center of mass energy $\sqrt{s} = 314 \text{ GeV}$ (currently $E_e = 27.5 \text{ GeV}$, so that $\sqrt{s} = 300 \text{ GeV}$). This corresponds to an electron beam energy of 52 TeV against a fixed target. The beams cross each other at zero angle in two interaction regions, occupied by the experiments H1 and ZEUS. The

bunch crossing occurs every 96 ns. The designed number of bunches in each beam is 210. To check beam related backgrounds about 10 bunches are left unpaired in each beam.

The HERA kinematics is represented in Fig. 9. The invariant kinematic variables of the semi-inclusive reaction $ep \rightarrow eX$ are:

$$Q^2 = -q^2 = -(k - k')^2 \quad (16)$$

$$x = \frac{Q^2}{2P \cdot q} \quad (17)$$

$$y = \frac{P \cdot q}{P \cdot k} \quad (18)$$

$$W^2 = (P + q)^2 \quad (19)$$

Two of them can be chosen as independent variables. Q^2 is the virtuality of the exchanged photon. The photoproduction regime is defined by low Q^2 , such that the photon is almost real. In this case we may regard HERA as a photon-proton collider, where the photons are emitted almost collinearly with the electron beam. The photon spectrum can be again evaluated with the Equivalent Photon Approximation, factorizing the vertex $e \rightarrow e\gamma$ in the flux factor of formula (5) with the kinematic limits given by (6) and (7), in which the variable z is substituted by y . Due to the asymmetric energies of the HERA beams the γp center of mass is boosted typically by two units of pseudorapidity η , defined as:

$$\eta = \frac{1}{2} \ln \frac{p + p_z}{p - p_z} = -\ln \left(\tan \frac{\theta}{2} \right) \quad (20)$$

This means that a particle going at 90° in the γp center of mass appears at about 15° in the HERA laboratory frame. In the following sections we will refer to forward or backward (rear) directions intending respectively the proton and the photon directions.

The photoproduction regime is experimentally defined in two ways:

- tagged photoproduction, when the scattered electron is detected at a very small angle. This can be done in both ZEUS and H1 by dedicated calorimeters placed near the beam line at several meters from the interaction point. The Q^2 acceptance extends in this case from 10^{-8} GeV^2 to 0.02 GeV^2 ;
- untagged photoproduction, defined by the antitagging condition that the scattered electron is not detected in the main calorimeter. This definition has been used by both the experiments. It corresponds to $Q^2 \leq 4 \text{ GeV}^2$, with median Q^2 about 10^{-4} GeV^2 .

In contrast the region of $Q^2 \geq 4 \text{ GeV}^2$ is the traditional Deep Inelastic Scattering (DIS) region, where the process in Fig. 9 is understood as a pointlike interaction between the electron and a quark constituent of the proton. In this regime the structure of the proton can be studied by exploiting the almost pointlike nature of the exchanged virtual photon. This region is experimentally defined by tagging the scattered electron in the

main calorimeter. The x variable represents in this context the momentum fraction of the struck quark relative to its parent proton.

The meaning of y is that of scaled photon energy: in the proton rest frame $0 < y = E_\gamma/E_e < 1$ and W is the photon-proton center of mass energy or equivalently the invariant mass of the hadronic final state. In the photoproduction regime these are related by $W \simeq \sqrt{sy}$. In comparison with previous photoproduction experiments, carried out with fixed targets, HERA enlarges by one order of magnitude the range of center of mass energies. Depending on the specific process the HERA experiments can span the whole range of W between 30 GeV and 300 GeV running at the nominal beam energies. Lower values of W could be accessed by reducing the energy of the proton beam.

In the tagged mode y (and hence W) is easily determined by measuring the energy of the scattered electron E'_e in the low-angle electron tagger by:

$$y = 1 - \frac{E'_e}{E_e} \quad (21)$$

In the untagged mode y can be determined from the measurement of the hadronic final state by the Jacquet-Blondel variable [41], defined as:

$$y_{JB} = \frac{\sum_{i=1}^{N_{cell}} (E - p_z)_i}{(E - p_z)_{tot}} = \frac{\sum_i E_i (1 - \cos \theta_i)}{2E_e} \quad (22)$$

where the sum runs over all the calorimeter cells, E_i being the energy contained in the i -th cell at polar angle θ_i with respect to the proton direction. y_{JB} gives a systematically lower value than the true y , mostly due to particles escaping detection inside the beam pipe in the photon direction or inactive material in front of the calorimeter, and is corrected by Monte Carlo detector simulation.

The final states produced in photoproduction events can be very diverse, from hadron-like minimum bias γp interactions to (quasi)elastic vector meson production, to the production of large p_T jets and heavy flavours. Detection of all those processes demands multipurpose detectors such as ZEUS and H1 with many capabilities and good overall performances.

4 The experiments ZEUS and H1

Both ZEUS and H1 have multipurpose detectors. Here only a brief description is given, more details can be found in [42, 43].

A longitudinal section of the central part of the ZEUS detector is shown in Fig. 10. Charged particles are measured by the inner tracking detectors: the vertex detector (VXD), the central tracking detector (CTD) and forward and rear tracking detectors (FDET, RTD). They operate in a magnetic field of 1.43 T produced by a thin superconducting solenoid. The VXD and the CTD are concentric cylindrical drift chambers

covering the angular region $15^\circ < \theta < 164^\circ$ (where θ is the polar angle with respect to the proton direction). The measured resolution for tracks going through all the CTD layers is: $\sigma_{p_T}/p_T = 0.005 p_T(\text{GeV}) \oplus 0.016$.

Surrounding the coil is the high resolution uranium-scintillator calorimeter (CAL), mechanically divided into three parts, the forward (FCAL), barrel (BCAL) and rear (RCAL) calorimeter. The calorimeter is compensating, the thickness of the uranium and scintillator tiles were optimized to achieve the best possible energy resolution for hadrons. It covers the angular region: $2.6^\circ < \theta < 176.1^\circ$, corresponding to 99.7% of the solid angle, with holes of $20 \times 20 \text{ cm}^2$ in the center of the forward and rear calorimeters to accomodate the HERA beam pipe. Each part of the calorimeter is subdivided into towers of transverse size $20 \times 20 \text{ cm}^2$ which are segmented longitudinally into one electromagnetic (EMC) and one or two hadronic (HAC) sections. In the electromagnetic section the readout cells have finer granularity of $5 \times 20 \text{ cm}^2$ (in FCAL and BCAL) or $10 \times 20 \text{ cm}^2$ (in RCAL). Each cell is read out by two photomultipliers. Under test beam conditions the energy resolution is $\sigma_E/E = 0.18/\sqrt{E}$ for electrons and $\sigma_E/E = 0.35/\sqrt{E}$ for hadrons, with E in GeV. The time resolution is better than 1 ns for energy deposits greater than 4.5 GeV.

Outside the uranium calorimeter a moderate resolution calorimeter (BAC), made of iron layers interleaved with proportional tubes, measures the tails of high energy jets and acts as a filter for muons. The muon detectors are also divided into three sections, covering the forward, the barrel and the rear regions. In the barrel and rear regions large chambers made of limited streamer tubes measure the position and the direction of muons in front and behind the iron yoke (BMUON, RMUON). The yoke is magnetized to 1.6 T to allow the momentum measurement for penetrating muons. In the forward direction a spectrometer (FMUON), made of two iron toroids, drift chambers and planes of limited streamer tubes, identifies muons and measures their momenta.

Charged particles scattered at very small forward angles and carrying a substantial fraction of the proton beam momentum are detected in the leading proton spectrometer (LPS). This is a set of six stations placed along the beam line at distances from 20 to 90 meters from the interaction point, using planes of silicon microstrip detectors very close to the proton beam. The track deflection induced by the magnets in the proton beam line is used to measure the momentum. The LPS measures a leading proton for fractional momentum $x_L \geq 0.4$ and $p_T \leq 1 \text{ GeV}$.

The luminosity is measured from the rate of the Bethe-Heitler process $ep \rightarrow e\gamma p$, whose cross section is large and calculable to high precision. Two lead-scintillator calorimeters placed downstream the electron beam pipe detect respectively the outgoing electron and the photon. The electron calorimeter lies at 35 m from the interaction point and accepts electrons with energy between 7 and 20 GeV scattered at angles up to about 5 mrad. The photon calorimeter is placed at 107 m from the interaction point and accepts photons produced at angles below 0.5 mrad. Bremsstrahlung events are tagged by the coincidence of the two calorimeters where the energies add up to the energy of the electron beam. The luminosity is calculated from the photon tagger alone.

Figure 11 shows a schematic view of the H1 detector. Charged particles are tracked by the central and forward tracking systems, both consisting of drift and multiwire proportional chambers. The momentum resolution achieved is $\sigma_{p_T}/p_T \approx 0.009 \cdot p_T(\text{GeV}) \oplus 0.015$ and the angular coverage is the same as for the ZEUS detector.

The tracking region is surrounded by a fine grained liquid argon calorimeter (LAr) with an electromagnetic section made of lead absorber plates and an outer hadronic section with steel absorber plates. Its angular coverage is $4^\circ < \theta < 153^\circ$. The energy resolution under test beam conditions is $\sigma_E/E = 0.12/\sqrt{E}$ for electrons and $\sigma_E/E = 0.50/\sqrt{E}$ for hadrons, with E in GeV. The calorimeter is not compensating and offline corrections are applied according to the shower shape and energy. Its segmentation varies as a function of the polar angle and is finer in the proton direction where, due to the asymmetry of the HERA beam energies, the particle density is higher. In this region the transverse cell size is as small as $3 \times 3 \text{ cm}^2$. The backward region $155^\circ < \theta < 176^\circ$ is covered by another calorimeter, which was primarily intended for the detection of the scattered electron in deep inelastic scattering. This consisted of a lead-scintillator sandwich with depth of $22.5X_0$ and energy resolution $\sigma_E/E = 0.10/\sqrt{E}$. From the 1995 data taking it has been replaced by a scintillating fiber calorimeter with photomultiplier readout.

The calorimeters are contained inside a superconducting solenoid providing a uniform magnetic field of 1.15 T for the inner tracking detectors. Outside the coil there is the iron yoke, which is instrumented with LST planes for the muon identification. Further muon chambers in front and behind the iron complete the muon detectors in the central region, while in the forward region muons are measured in a toroidal spectrometer similar to the one in ZEUS. The luminosity is measured in a similar way as in ZEUS, from the coincidence rate of two TlCl/TlBr crystal calorimeters.

HERA operation began in summer 1992 with electron beam energy of 26.7 GeV. Since 1994 positrons are run at energy of 27.5 GeV. The luminosity has continuously increased from year to year. In Fig. 12 the integrated luminosity delivered by HERA is shown as a function of time for the period 1992-1995. We review here the final results available at present, which have been obtained analyzing data taken up to the 1994 run.

5 Total γp cross section and its decomposition.

The high energy behaviour of total hadronic cross sections is related to fundamental properties of particle interactions. $p\bar{p}$ colliders have provided data up to a center of mass energy $\sqrt{s} = 1.8 \text{ TeV}$, demonstrating the logarithmic rise of the cross section [44, 45, 46]. Asymptotically this rise cannot violate the Froissart-Martin bound [47, 48], which states that total cross sections cannot grow faster than $\ln^2(s)$, as a consequence of unitarity. At HERA the γp cross section has been measured up to a center of mass energy of 200 GeV, an order of magnitude higher than previous photoproduction measurements from fixed target experiments [49].

The most popular approach to hadronic cross sections employs Regge theory ideas [50]. In this framework the simplest description is due to Donnachie and Landshoff [51]. They have been able to fit all the available cross section data (for $\sqrt{s} > 5$ GeV) using a parametrization inspired by Regge theory, of the form:

$$\sigma_{tot} = X s^{\epsilon} + Y s^{-\delta} \quad (23)$$

The first term arises from pomeron exchange and the second from reggeon exchange (ρ , ω , f , a). The exponents ϵ and δ are effective powers, summing effects of multiple pomeron or reggeon exchanges. Such effects are supposed to be small, therefore ϵ and δ are related to the intercepts of the pomeron and reggeon trajectories:

$$\alpha_P(t) = \alpha_P(0) + \alpha'_P \cdot t \quad (24)$$

$$\alpha_R(t) = \alpha_R(0) + \alpha'_R \cdot t \quad (25)$$

that is:

$$\epsilon = \alpha_P(0) - 1 = 0.0808 \quad (26)$$

$$\delta = 1 - \alpha_R(0) = 0.4525 \quad (27)$$

The pomeron has the quantum numbers of the vacuum, so that its coupling to a particle a and its antiparticle $\bar{a}$ are equal. Thus the coefficient X is set equal for $\sigma(ab)$ and $\sigma(\bar{a}b)$. This is a way of enforcing the Pommeranchuk theorem [52] in the fit. The universal rise of the cross sections with energy is interpreted by Donnachie and Landshoff as sign of the universality of something that is exchanged, the pomeron, which is sometimes also referred to as the “soft” pomeron. This simple parametrization becomes inconsistent at very high energies, violating the Froissart-Martin bound. However this takes place only at $\sqrt{s} > 10^{24}$ GeV, very far from the presently conceivable energies.

On the other hand several models have been based on perturbative QCD, attributing the rise of the cross section to the onset of “minijets” [53, 25]. In this context the total inelastic γp cross section is assumed to have a energy independent part, coming from soft non-perturbative interactions, and a QCD part rising with energy, due to the increase of gluons in the proton and in the photon at low partonic energy fractions. Predictions based on this approach depend on the parton distributions of the proton and the photon, the minimum transverse momentum down to which the perturbative calculation is assumed to be valid (p_T^{min}), and the probability for a photon to go into a hadronic state. These models use the eikonal formalism to ensure unitarity [54] and in general have a large number of unknown parameters.

The total γp cross section is the sum of quite different processes, represented in Fig. 13. Let us first divide diffractive (13/a-d) from non-diffractive processes (13/e). In diffractive processes there is no colour exchange between the proton and the hadronic state of the photon. In the figure they are represented to proceed through pomeron exchange. Assuming the validity of the VDM [2] for the transition $\gamma \rightarrow V$ ($V = \rho, \omega, \phi$) the following four classes are identified:

- elastic vector meson production $\gamma p \rightarrow Vp$ (Fig. 13/a). The truly elastic Compton scattering $\gamma p \rightarrow \gamma p$ has a cross section about two orders of magnitude smaller and can be neglected.
- photon diffractive dissociation $\gamma p \rightarrow Xp$ (Fig. 13/b). In this case the photon gives rise to a low mass hadronic system X with the same quantum numbers, while the proton stays almost untouched and is the leading particle in the final state.
- proton diffractive dissociation $\gamma p \rightarrow VY$ (Fig. 13/c). The photon converts to a vector meson and the proton breaks up into a low mass hadronic system Y.
- double diffractive dissociation $\gamma p \rightarrow XY$ (Fig. 13/d). Here both the photon and the proton dissociate to low mass hadronic systems.

In all cases the transverse momentum exchanged is generally low and the topology of the final state is characterized by large rapidity intervals (or *gaps*) without particles. This is expected if there is no colour flow between the interacting particles and is exploited as an experimental signature.

Non-diffractive processes (Fig. 13/e) are mostly soft ones, similarly to minimum bias events at hadron colliders. In this case colour exchange occurs and thus final state particles are distributed throughout the available phase space without significant gaps.

It should be clear that the different processes listed above are qualitatively quite different from one another. Experimentally, to trigger and select inclusive photoproduction events at HERA one needs a coincidence between tagging of the scattered electron in the low-angle electron taggers and activity in the main apparatus, at least a charged track or a minimum energy deposition. The detection efficiency for each of the photoproduction processes is quite different, thus complicating the measurement of the total cross section. Introducing the partial cross sections σ_i ($i=1,5$) for the five considered classes of reactions, with $\sigma(\gamma p \rightarrow X) = \sum_{i=1}^5 \sigma_i$, the observed number of events N_{ev} is given by:

$$N_{ev} = \mathcal{L} \Phi_{\gamma/e} A_e \sum_{i=1}^5 \epsilon_i \sigma_i \quad (28)$$

with $\mathcal{L}$ the integrated luminosity, $\Phi_{\gamma/e}$ the photon flux, A_e the efficiency to tag the low angle electron and ϵ_i the efficiency of the main detector for the i -th process. The photon flux is obtained by integrating expression (5) in the kinematic region corresponding to the low-angle electron tagger. The ϵ_i are calculated by Monte Carlo simulations of each different process. To reduce the systematic error it is important to determine separately each of the σ_i , otherwise one would have to rely on model dependent assumptions in the Monte Carlo, such as the relative magnitude of each contribution and its characteristics.

The H1 experiment has measured the total γp cross section [55] by short dedicated runs with special triggers in 1994. They took 24 nb^{-1} data with nominal vertex position and the same amount of data with vertex displaced by about 70 cm towards the forward

part of the detector. In fact the acceptance for all the diffractive processes increases if the position of the interaction vertex is shifted in this way. The modest integrated luminosity is already enough due to the large photoproduction cross sections. The partial cross sections for the diffractive reactions are determined from fits to selected distributions, related to the rapidity gaps in the pattern of the final state particles. This is done on the shifted vertex data. The double dissociation cross section (σ_{DD}) is assumed to be in the reasonable range $0 - 40 \mu\text{b}$. The non-diffractive cross section is then determined from nominal vertex data, giving as input in (28) the diffractive partial cross sections previously determined. The measured cross sections are summarized in table 1. The elastic cross section σ_{EL} is almost independent of the assumed value of σ_{DD} . Instead the single photon dissociation (σ_{GD}) and the single proton dissociation (σ_{PD}) cross sections depend markedly on σ_{DD} , but for any chosen value of σ_{DD} the photon dissociation cross section is found to be larger than the proton dissociation one. The dominant systematic error ($\sim 5\%$) in the result is on the acceptance of the electron tagger. This depends strongly on the electron beam optics, particularly on the offset and the tilt of the beam in the horizontal plane.

The total cross section as measured by H1 at an average c.m.s. energy $W \simeq 200 \text{ GeV}$ is shown in Fig. 14, together with previous data at lower energies [49] and a measurement from ZEUS [56]. The curves are predictions of Donnachie-Landshoff (DL) [51] and Abramowicz-Levin-Levy-Maor (ALLM) [57] parametrizations, both of which did not include HERA data. The ALLM is based on both γp and $\gamma^* p$ data at fixed target experiments. It allows a unified representation of photon-proton interactions with Q^2 from 0 up to the DIS regime. A DL fit taking into account the CDF measurement [46] gives the exponent $\epsilon = 0.11$ in (23). The HERA data are well accommodated in the soft pomeron phenomenology expressed by these parametrizations, thus supporting the VDM and the universality of the rise in the cross sections at high energy.

Minijet models give predictions spread over a larger range due to uncertainties in the different parameters involved [58]. The present HERA results can be brought into accordance with calculations having a not too small p_T^{min} ($\geq 2 \text{ GeV}$) and a moderately rising gluon density in the photon, but strong conclusions cannot be drawn.

In table 2 the diffractive partial cross sections measured by H1 are compared to predictions of several theoretical models, based on different assumptions about the structure and dissociation of the photon and the proton. CKMT [59] is a calculation using Regge theory plus absorptive corrections for all the different processes. The measured cross sections are derived fixing $\sigma_{DD} = 15 \mu\text{b}$, in agreement with the models. The elastic cross section is correctly predicted by all the models. The photon dissociation cross section is measured to be three times larger than the proton dissociation one, in agreement with predictions of CKMT. Instead SaS [60] and GLM [61] predict $\sigma_{PD} > \sigma_{GD}$.

6 Elastic vector meson production

The elastic reaction $\gamma p \rightarrow Vp$ ($V = \rho, \omega, \phi, J/\psi, \dots$) represented in Fig. 13/a is equivalent to a hadronic elastic interaction $Vp \rightarrow Vp$, assuming the validity of the VDM. The optical theorem relates the total Vp cross section to the imaginary part of the forward elastic scattering amplitude:

$$\sigma_{Vp}(s) = \frac{\text{Im } T(s, t=0)}{s} \quad (29)$$

where t is the square of the momentum transfer. Soft pomeron phenomenology thus gives straightforward predictions on the elastic cross sections [62]. The elastic cross section is predicted to rise slowly with the c.m.s. energy and to be dominated by forward scattering, with a sharp peak at $t = 0$ of roughly exponential behaviour:

$$\frac{d\sigma}{d|t|} \simeq A e^{-b|t|} \quad (30)$$

The b -slope is related to the radius of the hadronic interaction and it can be understood in the context of a simple geometrical model. In a fixed target configuration, for small angle of scattering $t \simeq -(p\theta)^2$, where p is the incident beam momentum and:

$$\frac{d\sigma/dt}{(d\sigma/dt)_{t=0}} = e^{-b|t|} \simeq 1 - b(p\theta)^2 \quad (31)$$

In the classical optical diffraction of light from a circular aperture of radius R the intensity of light is given by:

$$\frac{I}{I_0} \simeq 1 - \frac{R^2}{4}(k\theta)^2 \quad (32)$$

where k is the wave number of the light. Comparing these two expressions one has a relation between the slope parameter and the radius of the interaction:

$$b = \frac{R^2}{4} \quad (33)$$

For a typical radius of the strong interaction $R = 1/m_\pi$ (with m_π the pion mass) the last expression gives $b \simeq 12.5 \text{ GeV}^{-2}$. This is in the measured range of values for elastic scattering of hadrons at high energy. The t spectrum is predicted to exhibit a dip followed by a secondary diffraction maximum, as for light diffraction. This is in fact observed in high energy pp and $p\bar{p}$ elastic scattering [63]. Regge theory predicts a weak dependence of the b -slope on the center of mass energy, referred to as shrinkage, of the kind:

$$b = b_0 + 2\alpha'_{\mathbb{P}} \log \frac{s}{s_0} \quad (34)$$

This effect actually allows the determination of the slope of the pomeron trajectory in (24): $\alpha'_{\mathbb{P}} \simeq 0.25 \text{ GeV}^{-2}$.

Fixed target experiments have studied the elastic vector meson photoproduction up to $W \approx 20$ GeV. Light (ρ , ω , ϕ) vector meson data [1, 64] have been found consistent with soft pomeron phenomenology and the VDM. Elastic J/ψ production [65] cross sections were overestimated by VDM by more than an order of magnitude, but other predictions like the energy dependence agreed with data within the errors.

HERA experiments have measured the elastic reaction $\gamma p \rightarrow Vp$ for $V = \rho$ [66, 67, 68], ω [69], ϕ [70], J/ψ [71, 72, 73, 74]. These measurements are complemented by similar ones carried out in the DIS regime [75, 76]. The reconstruction of the vector meson decays:

$$\begin{aligned}\rho^0 &\rightarrow \pi^+\pi^- \\ \omega &\rightarrow \pi^+\pi^-\pi^0 \\ \phi &\rightarrow K^+K^- \\ J/\psi &\rightarrow e^+e^-, \mu^+\mu^-\end{aligned}$$

has allowed the measurements at W from 40 to 100 GeV for light mesons, from 30 to 150 GeV for J/ψ . One of the hardest experimental tasks is to trigger on such elastic events. In fact both the outgoing electron and the proton are generally not tagged. Then only the decay products of the meson decay can be observed in the detector. The typical topology of these events is of two charged tracks in the photon hemisphere (plus an electromagnetic calorimeter cluster due to the π^0 in ω decays). The acceptance in W is determined by the detector geometry and trigger.

In tagged photoproduction events the ρ production has also been measured without reconstruction of the decay at $\langle W \rangle \simeq 200$ GeV, from fits to distributions of the hadronic final state by comparison to Monte Carlo distributions for ρ production [56, 67]. At these high W values the decay pions are boosted in the photon direction outside the acceptance of the tracking detectors and their reconstruction is carried out by the calorimeter. In this case the worse spatial and energy resolutions have prevented measurements of differential distributions.

The kinematic variables W and t can be easily determined from the vector meson, reconstructed from its decay products, in the limit of $Q^2 \approx 0$. In fact in this case $(p_z)_\gamma \simeq -E_\gamma$ and:

$$W^2 \simeq 4E_\gamma E_p \simeq 2(E - p_z)_V E_p \quad (35)$$

$$t \simeq -(p_T^2)_V \quad (36)$$

where the subscript V indicates the vector meson. The main background to the elastic reactions comes from events where the proton dissociates (fig. 13/c). This can be reduced by requiring a very low energy deposit in the forward part of the calorimeter ($E < 1$ GeV). The residual background is estimated studying the effect of changing this cut in comparison to Monte Carlo simulations of the relevant diffractive process. In the final samples it is generally 10 – 30 % and is statistically subtracted.

Proton dissociation can be completely avoided by detecting the leading proton scattered at a very small angle. This has been done by ZEUS using the leading proton

spectrometer (LPS), which directly measures the momentum of the leading proton with high accuracy (with the configuration the detector had in 1994 run: 0.4% on the longitudinal component, ≈ 5 MeV on p_T). For truly elastic events the momentum of the proton is reduced by less than 0.2% and thus events are selected with $0.98 < x_L < 1.02$, where $x_L = p'/p$ is the ratio between outgoing and incoming proton momentum (x_L can be measured greater than unity due to the experimental resolution). One is thus guaranteed that the proton scatters elastically and t is directly measured. Owing to the energy-momentum balance the Q^2 can also be determined in this case. In fact in the elastic reaction the knowledge of the p_T of the vector meson and of the scattered proton allows a determination of the p_T of the untagged scattered electron, and from this the Q^2 :

$$Q^2 = \frac{p_T^e}{1 - y} \quad (37)$$

where $y \simeq W^2/s$. The measured $d\sigma/dt$ for elastic ρ^0 production is shown in Fig. 15. A fit of the form (30) gives $b = 9.8 \pm 0.8$ (stat.) ± 1.1 (syst.) GeV^{-2} , with dominant systematic uncertainties on the LPS acceptance and the beam spread in the transverse momentum.

HERA measurements of the slope for ρ elastic photoproduction are shown in Fig. 16 in comparison with fixed target results. They agree with a slow shrinkage of the diffractive peak as predicted by the soft pomeron formula (34). This is also true for the measurements of the other light vector mesons, summarized in table 3. Recalling that b is related to the radius of the interaction, the values in table 3 indicate a smaller radius for ϕp as compared to ρp interaction.

The integrated elastic cross sections for ρ , ω , ϕ , J/ψ photoproduction measured at HERA as functions of W are shown in Fig. 17 together with data from fixed target experiments. In the soft pomeron model [62] one expects:

$$\sigma_{\gamma p \rightarrow V p}(W) \propto \frac{W^{4\epsilon}}{b(W)} \simeq W^{0.22} \quad (38)$$

where ϵ is given by (26) and $b(W)$ is given by (34) with $s = W^2$. This is in good agreement with data on light vector mesons. The same model predicts for the total photoproduction cross section a dependence $W^{2\epsilon} \simeq W^{0.16}$, which also agrees with data, as shown.

Another characteristic of the elastic vector meson production at fixed target energies is the so-called s-channel helicity conservation (SCHC). For real or quasi-real photons it means that the transverse polarization of the photon is transferred to the vector meson. The polarization of the vector meson can be experimentally determined from the angular distributions of the decay products, which depend on the spin-density matrix elements [77]. The analyses reveal in all cases that SCHC continues to hold at the HERA energies.

This homogeneous situation changes dramatically when one turns to the elastic production of J/ψ . Coming back to Fig. 17, the J/ψ elastic cross section is steeply rising with W and the Donnachie-Landshoff model fails, predicting a slow rise as for the light vector mesons. In Fig. 18/a only the ZEUS data are shown. The fit with a function W^δ

gives $\delta = 0.92 \pm 0.14 \pm 0.10$. Thus even in this restricted range the soft pomeron model is excluded by data. Instead other two pomeron models are found to give a good description of the total cross section [78, 79] (Fig. 18/b). They involve either a scale dependent pomeron intercept or scale dependent pomeron couplings and mass threshold effects. The data can also be reproduced by models based on perturbative QCD [80, 81, 82], where the pomeron is considered as a system of two interacting gluons, or gluon ladder, as in Fig. 19. In these models the cross section is proportional to the square of the gluon density in the proton. For a singular gluon density at small x , rising like:

$$x^{-\lambda} \quad \text{as } x \rightarrow 0 \quad (39)$$

as implied by HERA F_2 measurements [33, 34], a steep rise is predicted with increasing W . HERA F_2 data are well described by the MRS(A') parametrization [83], which corresponds to a power $\lambda \approx 0.2$ in (39), and by the GRV parametrization [84] corresponding to $\lambda \approx 0.3 - 0.4$. In the Ryskin model [80] the effective energy scale $\bar{q}$ and momentum fraction $\bar{x}$ at which the gluon distribution is tested are given by:

$$\bar{q}^2 = \frac{Q^2 + m_{J/\psi}^2 - t}{4} \quad (40)$$

$$\bar{x} = \frac{Q^2 + m_{J/\psi}^2 - t}{W^2} \quad (41)$$

For $Q^2 \approx 0$, $t \approx 0$ the only hard scale is represented by the J/ψ mass and the applicability of perturbative QCD relies on it. From (40,41) one has: $\bar{q}^2 \simeq 2.5 \text{ GeV}^2$ and $5 \cdot 10^{-4} \leq \bar{x} \leq 5 \cdot 10^{-3}$. Due to the quadratic dependence on the gluon density the shape of the cross section as a function of W is very sensitive to different proton parton density parametrizations. However the normalization of the theoretical result suffers presently from quite large uncertainties. In Fig. 18/b the elastic J/ψ data are compared to the prediction of the Ryskin model with input gluon density given by MRS(A'). A good agreement is found, while the steeper behaviour of GRV has been reported to overshoot HERA data [73].

H1 has determined the slope of the J/ψ p_T^2 distribution by fitting data with $p_T^2 \leq 1 \text{ GeV}^2$ to an exponential $e^{-b'p_T^2}$ in the range $30 < W < 150 \text{ GeV}$, achieving $b' = 4.0 \pm 0.2 \pm 0.2 \text{ GeV}^{-2}$. The error in the slope due to using p_T^2 instead of t is evaluated from Monte Carlo to be -10% . No clear evidence for shrinkage is obtained dividing the sample in W bins, mainly due to the still limited statistics. A consistent result comes from the ZEUS analysis, which also corrects explicitly the p_T^2 differential cross section to obtain $d\sigma/d|t|$, shown in Fig. 20. Fitting over the range $|t| < 1 \text{ GeV}^2$ with an exponential shape $e^{-b|t|}$ gives $b = 4.6 \pm 0.4_{-0.6}^{+0.4} \text{ GeV}^{-2}$, which is consistent with the slope values from fixed target experiments [65].

H1 also measured the cross section for J/ψ production with proton dissociation, exploiting their forward detectors. This turns out to be of the same order of the elastic cross section, in a similar range of W . The p_T^2 distribution gives a slope: $b' = 1.6 \pm 0.3 \pm 0.1 \text{ GeV}^{-2}$, a factor of 2.5 smaller than for pure elastic scattering.

The study of the decay angular distributions of the J/ψ (both elastic and with proton dissociation) shows consistency with s-channel helicity conservation, i.e. the J/ψ , like lighter mesons, is mainly transversely polarized.

Diffraction production of ψ' has been observed by H1 [73] in the decay chain $\psi' \rightarrow J/\psi \pi^+\pi^-$, $J/\psi \rightarrow \mu^+\mu^-$. The rate of its production compared to J/ψ is found to be 0.20 ± 0.09 , in agreement with previous measurements at fixed target experiments.

Elastic vector meson production has also been measured at high Q^2 for ρ^0 , ϕ and J/ψ [75, 76]. Preliminary results exist for low and high- t ρ^0 photoproduction with proton dissociation [85]. These data, compared to fixed target data, suggested a hard production mechanism when a high energy scale is present in the interaction, be it a high mass (as the J/ψ mass) or high Q^2 or t . However recent results from the E665 Collaboration [86] appear at variance with the previous fixed target data. The experimental situation for light vector mesons is still to be clarified. Thus vector meson production at HERA allows to study the transition from a non-perturbative description of the pomeron (the soft pomeron), to the hard perturbative pomeron.

7 Hard photoproduction and QCD

Hard photoproduction processes at HERA are of particular interest. The large cross sections and the range of high center of mass energies allow precise studies of the photon structure in a way complementary to the $e\gamma$ deep inelastic scattering. Moreover the QCD dynamics and the peculiar features of photon induced reactions can be tested. The hard scale is provided by the highest transverse momentum of the produced particles or jets in the final state. Application of perturbative QCD requires that this scale is at minimum a few GeV. As mentioned earlier, in leading order of QCD two classes of processes contribute to the production of high p_T particles or jets. The photon may interact directly with a parton in the proton, as in Fig. 21/a, or it may first fluctuate into a hadronic state as in Fig. 21/b and then act as source of partons, which scatter off partons in the proton. In the first case, known as *direct* photon, the whole photon momentum enters in the hard subprocess and the final state consists of two jets balancing each other in p_T plus the proton remnant and the scattered electron, emerging with small p_T . In the second case, known as *resolved* photon, only a fraction of the photon momentum participates in the hard process and the final state has in addition a photon remnant, keeping approximately the original photon direction. The two diagrams represented in Fig. 21 are of the same order in the coupling constants, $\alpha_{em}^2\alpha_s$. In fact the resolved diagram involves the photon parton densities which are of order α_{em}/α_s , as we discussed in section 2, bringing the power counting to the same result.

The kinematics of final state particles or jets are generally specified by their transverse momentum p_T with respect to the beam axis (or equivalently the transverse energy E_T) and by the pseudorapidity η . The definition of a jet requires a jet algorithm at both the experimental and the theoretical level. We will describe in some detail the relevant

definitions. At the Born level the knowledge of E_T ($E_{T1} = E_{T2}$), η_1 and η_2 for the two final state partons, identified with the final jets, allows one to obtain the energy fractions x_γ and x_p of the initial partons from the photon and the proton respectively. Let us write the four-momentum balance in the hard $2 \rightarrow 2$ subprocess:

$$yx_\gamma \mathbf{k} + \mathbf{x}_p \mathbf{P} = \mathbf{j}_1 + \mathbf{j}_2 \quad (42)$$

where $\mathbf{k}$, $\mathbf{P}$, $\mathbf{j}_1$, $\mathbf{j}_2$ are respectively the four-momenta of the incoming electron and proton and of the two final partons. From this one obtains:

$$x_\gamma = \frac{E_T}{2E_\gamma}(e^{-\eta_1} + e^{-\eta_2}) \quad (43)$$

$$x_p = \frac{E_T}{2E_p}(e^{\eta_1} + e^{\eta_2}) \quad (44)$$

This holds only at LO. At this level direct photon events have $x_\gamma = 1$ and resolved ones $x_\gamma < 1$.

The distinction between direct and resolved photon diagrams becomes theoretically ambiguous in NLO of QCD. Both components are related to each other through the factorization scale M_γ at the photon leg. The M_γ dependence of the NLO direct cross section cancels against the M_γ dependence in the resolved cross section via the photon structure function. In a consistent NLO calculation both the components have to be summed using the same M_γ scale. In general one defines observables x_γ^{OBS} and x_p^{OBS} which are determined from the two highest E_T jets in the event:

$$x_\gamma^{OBS} = \frac{E_{T1}e^{-\eta_1} + E_{T2}e^{-\eta_2}}{2E_\gamma} \quad (45)$$

$$x_p^{OBS} = \frac{E_{T1}e^{\eta_1} + E_{T2}e^{\eta_2}}{2E_p} \quad (46)$$

Direct and resolved photon events can be experimentally defined by a cut on x_γ^{OBS} when two or more jets are measured in the final state [87, 88].

The cross section for n-jet production is expressed formally as a convolution of the partonic cross section with the photon and proton parton densities:

$$\begin{aligned} d\sigma(e p \rightarrow e \text{ jets } X) &= \int_0^1 dy \Phi_{\gamma/e}(y) \times \\ &\times \sum_{a,b} \int_0^1 dx_\gamma \int_0^1 dx_p f_{a/\gamma}(x_\gamma, M_\gamma^2) f_{b/p}(x_p, M_p^2) d\hat{\sigma}(a b \rightarrow \text{jets}) \end{aligned} \quad (47)$$

where a and b are the parton types from γ and p , and M_γ^2 , M_p^2 the factorization scales for the photon and proton parton densities. For a direct photon $a = \gamma$ and formally $f_{\gamma/\gamma}(x_\gamma) = \delta(1 - x_\gamma)$.

For the production of a particle h the inclusive cross section is expressed by introducing the fragmentation function $D_{h/c}(z)$, which gives the probability to obtain h from a final state parton c , with momentum fraction $z = p_h/p_c$. It can be written:

$$d\sigma(e p \rightarrow e h X) = \int_0^1 dy \Phi_{\gamma/e}(y) \times \quad (48)$$

$$\times \sum_{a,b,c} \int_0^1 dx_\gamma \int_0^1 dx_p \int_0^1 dz f_{a/\gamma}(x_\gamma, M_\gamma^2) f_{b/p}(x_p, M_p^2) D_{h/c}(z, M_f^2) d\hat{\sigma}(a b \rightarrow c X)$$

where M_f^2 is the factorization scale of the fragmentation function, which is usually set to the p_T^2 of the produced particle. The fragmentation functions need to be parametrized from experimental results [89].

The validity of equations (47) and (48) rests on the QCD factorization theorems (for a review see [90]), which state that universal parton distribution functions can be defined for a given hadron independently from the process. Thus comparing QCD calculations with experimental data may serve to constrain the parton distributions or, when the latter have negligible uncertainties, to test the parton dynamics.

7.1 Inclusive charged particle distributions

Inclusive distributions of charged particles in photoproduction have been measured by both H1 [91] and ZEUS [92]. In Fig. 22 the transverse momentum distributions are shown averaged over the pseudorapidity interval $-1.2 < \eta < 1.4$ (corresponding to the region $-3.2 < \eta^* < -0.6$ in the γp center of mass frame, in the photon hemisphere) as measured by ZEUS at $\langle W \rangle = 180$ GeV for tagged photoproduction events. The events have been separated in a non diffractive sample and two diffractive samples with different average values of the diffractive system mass M_X of 5 and 10 GeV. The separation is done on an event by event basis, labelling as diffractive the events with a rapidity gap around the proton beam direction larger than a fixed cut. Soft interactions of hadrons can be described by thermodynamic models [93], which predict an approximately exponential p_T spectrum of the kind:

$$\frac{1}{N_{ev}} \frac{d^2 N}{dp_T^2 d\eta} = \exp \left(a - b \sqrt{p_T^2 + m_\pi^2} \right) \quad (49)$$

where m_π is the pion mass. This expression is fitted to the ZEUS data in the range $0.3 < p_T < 1.2$ GeV resulting in the solid lines. The fitted values of the slope b are compared to results from pp and $p\bar{p}$ data as a function of the center of mass energy in Fig. 23. The slope of the ZEUS non-diffractive spectrum agrees with data from hadron-hadron scattering at similar energies. The diffractive slopes agree better with hadronic data taken at a lower energy: here they are plotted at 5 and 10 GeV, the values of the invariant mass of the dissociated photon, in agreement with data on proton diffractive dissociation at hadron colliders [63, 94].

The p_T spectrum for non-diffractive events in Fig. 22 deviates from an exponential at high p_T values. This is expected from QCD as a result of hard scattering between constituent partons. The high p_T behaviour can be approximated by a power law:

$$\frac{1}{N_{ev}} \frac{d^2 N}{dp_T^2 d\eta} = A \left(1 + \frac{p_T}{p_{T0}} \right)^{-n} \quad (50)$$

with $p_{T0} = 0.54$ GeV and $n = 7.25$. In Fig. 24 HERA data are compared to data from the WA69 [95] fixed target photoproduction experiment at $\langle W \rangle = 18$ GeV. This shows that the p_T spectrum becomes harder as the center of mass energy increases. The figure also shows fits of the form (50) to $p\bar{p}$ data from UA1 and CDF at several different energies [96, 97]. The p_T spectrum for photoproduction at HERA is clearly harder than the one from $p\bar{p}$ interactions at a similar energy, and is in fact similar to $p\bar{p}$ at $\sqrt{s} = 900$ GeV.

High energy γp and $p\bar{p}$ interactions show a strong similarity for the production of particles at low p_T , while the rate of high p_T particles is quite different, revealing the two-fold nature of the photon. In fact the most appealing reason for the observed difference is that at high p_T the pointlike coupling of the photon becomes important: thus γp interactions are not just like πp , instead direct and anomalous processes may occur. Other possible explanations could be the different pseudorapidity ranges used by the various experiments ($|\eta| < 2.5$ for UA1, $|\eta| < 1$ for CDF, $-3.2 < \eta < -0.6$ for ZEUS) or harder parton distributions in mesons (to which the photon converts according to the VDM) than in baryons.

HERA data have also been compared to a NLO QCD calculation [98] and are in good agreement in the region of high p_T . The high p_T inclusive particle cross section has recently been considered an important tool to extract precise parton distributions in the photon in the poorly known regions of $x_\gamma > 0.8$ and $x_\gamma < 0.05$ [99]. It has the advantage of being insensitive to possible multiple interactions or soft underlying event effects, discussed in section 7.3, as opposed to jet measurements.

7.2 Jets

Apart from the long tail in the p_T distribution of particles, the observation of jets is a direct means to establish the occurrence of hard scattering between constituent partons. A jet is a bunch of collimated particles coming from the fragmentation of a high energy quark or gluon. Jet measurements need a jet definition criterion or jet algorithm. Until now cone algorithms [100, 101] have been used more widely in photoproduction at HERA, given the framework similar to hadronic collisions.

Experimentally one starts from the calorimeter cells with energies above a threshold. For each cell the pseudorapidity η and azimuth ϕ are determined from the segment joining the interaction vertex to the geometric center of the cell. Each cell with transverse energy above a few hundred MeV is considered as a possible seed for the jet finding. The seeds are combined if their distance in the $\eta - \phi$ space, $R = \sqrt{\Delta\phi^2 + \Delta\eta^2}$, is less than some

cut (usually 1 or sometimes 0.7). Then a cone of radius R is drawn around each seed and the energy of all the included cells is summed up in a cluster. The cluster axis is defined along the Snowmass convention [101] from the E_T -weighted mean of the cells inside the cone. A new cone of radius R is then drawn around the calculated axis of the cluster and the axis is recalculated. The procedure is iterated until stability is reached. At the end it may happen that two clusters overlap. In this case if the shared transverse energy is more than 75% of the total E_T of one of the clusters they are merged, otherwise the common cells are assigned to the nearest one. In the end a cluster is called a jet if its transverse energy exceeds a minimum value. At HERA this is set typically in the range of 6 – 8 GeV.

Inclusive jet production has been measured by ZEUS [102] for $E_T^{jet} > 8$ GeV in the laboratory pseudorapidity range $-1 < \eta^{jet} < 2$, from 0.55 pb $^{-1}$ of untagged data ($Q^2 < 4$ GeV and $0.2 < y < 0.85$). Jets have been defined with a cone radius $R = 1$. Similar measurements have been reported by H1 [103] from a lower statistics of tagged data (290 nb $^{-1}$) with $Q^2 < 0.01$ GeV 2 and $0.25 < y < 0.7$. Fig. 25 shows the differential cross section $d\sigma/dE_T^{jet}$ integrated over two η ranges: $-1 < \eta^{jet} < 2$ and $-1 < \eta^{jet} < 1$. Data are corrected to the hadron level for detector effects by a complete detector simulation.

NLO QCD calculations of inclusive jet cross sections have been carried out by several groups [104, 105, 106, 107, 108]. These calculations involve at most three partons in the final state, from which jets are defined by the same cone algorithm as used for data. NLO corrections can be very large, up to a factor of two. This is reflected in a strong dependence of the LO results upon variations in the energy scale at which the strong coupling constant is evaluated or in the factorization scales M_γ^2 and M_p^2 . In LO these scales are often set at about the p_T^2 or $(p_T/2)^2$ of the hard jets. For those values the size of the NLO corrections is about its minimum. The stability of the NLO results against variations of the scales is much improved. The NLO curves plotted in Fig. 25 [106] are parton level results, not corrected for hadronization. They are consistent with the data.

Fig. 26 presents $d\sigma/d\eta^{jet}$ for jets with E_T^{jet} greater than 8, 11 or 17 GeV. Comparison with the theoretical NLO results [106] shows a preference for the GS parametrization over GRV in the region $\eta^{jet} \leq 0$, where the contribution from high x_γ partons is important. This is the photon fragmentation region, where the calculation is most reliable, thus giving a handle to test the photon structure. In the region $\eta^{jet} \geq 1$ the data, particularly at the lowest E_T^{jet} , are systematically above the predictions. Here the fragmentation corrections are sizeable and moreover the data are biased by a pedestal energy which has not been subtracted. This is thought to arise from a combination of soft and semi-hard interactions between the beam remnants in resolved photoproduction and it will be subject of a further discussion in the next section. A thorough understanding of this region is essential to carry out quantitative QCD tests in the low x_γ region accessible to HERA measurements ($x_\gamma \geq 0.01$).

The largest experimental errors are due to the absolute energy scale of the calorimeters, whose uncertainty is within $\pm 5\%$ for the measurement of hadronic jets in both ZEUS and H1. This has been determined comparing real data and Monte Carlo simulated events.

H1 studied the E_T imbalance between the scattered electron and the hadronic jet in high Q^2 events. ZEUS studied the ratio between E_T^{jet} (measured by the calorimeter) and the summed p_T of the charged tracks associated with the jet (measured by the central tracking detector), for jets with $|\eta^{jet}| < 1$; for jets with $1 < \eta^{jet} < 2$ the E_T imbalance has been studied in dijet events with the second jet in the central region. Due to the exponential fall of the jet cross section with increasing E_T^{jet} , the 5% energy scale error translates into a dominant systematic uncertainty of about 20% on the normalization of the cross sections. This uncertainty is almost completely correlated from point to point in figures 25 and 26 and is indicated as a shaded band. It has to be interpreted as the maximum systematic shift that might be applied overall. The cross section measurements could then move all up or down of the indicated amount.

It is expected from QCD that jets become narrower with increasing energy. The jet shape, that is the transverse energy flow versus $\Delta\phi$ or $\Delta\eta$, is approximately gaussian around the position of the jet axis. The full width Γ at half maximum of a jet is expected to decrease as $1/E_T^{jet}$ [109]. H1 has measured the dependence of Γ on the scaled E_T of the jet, shown in Fig. 27. The height of the gaussian is determined after subtraction of the pedestal energy. The jet transverse energy is normalized to the ep center of mass energy according to [109]. H1 data are compared to similar measurements from jet profiles in $p\bar{p}$ interactions [110]. The decrease of Γ with increasing E_T^{jet} is apparent and, within the errors, γp and $p\bar{p}$ jets show the same behaviour.

Direct and resolved photon samples have been experimentally defined for the first time by a cut on the x_γ^{OBS} variable (45) in events with at least two reconstructed jets by ZEUS [87, 88]. The observed x_γ^{OBS} distribution after the selection cuts is shown in Fig. 28. It is compared to the predictions of two Monte Carlo programs, HERWIG [111] and PYTHIA [112], which include LO QCD matrix elements plus parton showers and hadronization models. Resolved and direct photon processes, as implemented in the Monte Carlos, populate different x_γ^{OBS} regions. The peak at high values of x_γ^{OBS} is clearly attributed to direct photon processes. Its shift from $x_\gamma^{OBS} = 1$ is due to higher order QCD corrections and fragmentation effects, which are simulated in the Monte Carlos. Given this clear separation direct and resolved photon processes can be operatively defined by a cut at $x_\gamma^{OBS} = 0.75$. In the low x_γ^{OBS} region the Monte Carlo curves fall considerably below the data. The reason is the energy excess observed in the forward η region in comparison with the Monte Carlo expectations, which is discussed in the next section.

Dijet cross sections have been measured by ZEUS separately for $x_\gamma^{OBS} > 0.75$ and $x_\gamma^{OBS} < 0.75$ from 0.55 pb⁻¹ of untagged data [88]. Jets have been required to have $E_T^{jet} > 6$ GeV. Moreover a cut on the pseudorapidity separation between the two jets has been applied: $|\Delta\eta| = \eta_1 - \eta_2 < 0.5$. The cross section has been measured in terms of $\bar{\eta} = (\eta_1 + \eta_2)/2$, the average pseudorapidity of the jets. Assuming two jets with the same E_T^{jet} the kinematic variables x_γ^{OBS} and x_p^{OBS} can be expressed as:

$$x_\gamma^{OBS} = \frac{E_T^{jet} e^{-\bar{\eta}}}{E_\gamma} \cosh \frac{\Delta\eta}{2} \quad (51)$$

$$x_p^{OBS} = \frac{E_T^{jet} e^{\bar{\eta}}}{E_p} \cosh \frac{\Delta\eta}{2} \quad (52)$$

For $\Delta\eta = 0$ the hyperbolic cosine takes its minimum value of unity and thus for given E_T^{jet} and $\bar{\eta}$ the minimum values of x_γ^{OBS} and x_p^{OBS} are probed [113]. Moreover there is a strong correlation between $\bar{\eta}$ and x_p^{OBS} in the direct cross section and between $\bar{\eta}$ and $y x_\gamma^{OBS}$ in the resolved cross section. In Fig. 29 $d\sigma/d\bar{\eta}$ is shown for events defined as direct ($x_\gamma^{OBS} > 0.75$), together with results of a LO QCD calculations using GS2 parton distributions for the photon and different parametrizations for the proton. The agreement is reasonable and improves when comparing with a QCD Monte Carlo allowing for transverse momentum of the incoming partons, parton showers and hadronization effects. NLO QCD calculations have become available only recently. The first results compared to ZEUS data had resolved diagrams calculated only at LO [114, 108]. These calculations improved the agreement with data. Moreover they revealed an interesting sensitivity of the dijet cross section at high x_γ^{OBS} on the quark content of the photon, with data preferring GS over GRV parametrizations.

The resolved cross section ($x_\gamma^{OBS} < 0.75$) is shown in Fig. 30. Data are compared to a LO calculation using MRS(A) proton parton distributions and different parametrizations for the photon. Here only the shape can be reproduced by the theoretical curves, the normalization is below the data by a factor of 1.5 to 2 (except for LAC3 which is excluded by independent measurements from TRISTAN, as we showed at the end of section 2). This discrepancy can again be attributed to underlying soft or semi-hard interactions between the beam remnants.

Complete NLO calculations for dijet cross sections have been performed very recently [115] and compared to preliminary ZEUS data from a larger data sample. They obtain a good agreement for direct photon cross sections and even for resolved photon provided a minimum $E_T^{jet} > 11$ GeV. For jets with lower E_T^{jet} the comparison is still not good and the possibility of multiple interactions is thus confirmed on a more solid base.

Besides the sensitivity to photon parton distributions, jet data can test the QCD dynamics of the hard parton scattering. In the dijet analysis described above, the cut $|\Delta\eta| < 0.5$ constrained the angle θ^* between the jet-jet axis and the beam axis in the dijet center of mass system to be close to 90° . In fact one gets:

$$\cos\theta^* = \tanh\left(\frac{\Delta\eta}{2}\right) \quad (53)$$

Experimentally one can measure only the absolute value of $\cos\theta^*$ because the two jets are indistinguishable. Different angular distributions are expected for direct and resolved processes. Direct processes, as the diagram in Fig. 21/a, have a quark propagator in the s , t or u channel, with t and u channel processes dominating. The dominant resolved processes $gg \rightarrow gg$, $qg \rightarrow qg$, $qq \rightarrow qq$, as the diagram in Fig. 21/b, have t or u channel gluon exchange. Due to the different spin of the propagators, the angular dependence of the cross section is thus approximately $(1 - |\cos\theta^*|)^{-2}$ for resolved processes and $(1 - |\cos\theta^*|)^{-1}$ for direct processes. A steeper cross section is then expected at small scattering

angle for resolved processes. This property is expected to be preserved even in NLO calculations [116]. The ZEUS experiment has measured the angular distribution in dijet events with $E_T^{jet} > 6$ GeV and $|\bar{\eta}| < 0.5$ [117]. The last cut keeps events with small boost of the dijet system in the HERA frame, which have the jets well inside the calorimeter acceptance:

$$\bar{\eta} \simeq \eta_{boost} = \frac{1}{2} \ln \left(\frac{E_p x_p}{E_\gamma x_\gamma} \right) \quad (54)$$

A cut on the jet-jet invariant mass is applied at $M_{jj} > 23$ GeV, to avoid the bias due to the E_T^{jet} cut. The resulting $d\sigma/d|\cos\theta^*|$ is shown in Fig. 31 for direct and resolved events, defined as before by the cut on x_γ^{OBS} . There is good agreement between data and theory. The different shapes are not an artefact of the x_γ^{OBS} cut. Monte Carlo studies have confirmed that the shape is a characteristic of the spin of the propagator: even removing the x_γ^{OBS} cut resolved photon events generated with Monte Carlo maintain the same shape.

7.3 Underlying event energy

Let us come now to the problem of the observed pedestal energy. Jet shapes are shown in Fig. 32/a-b for direct and resolved event samples. Here the transverse energy flow is plotted as a function of the pseudorapidity distance from the jet axis. In the direct case ($x_\gamma^{OBS} > 0.75$) the jet shape is well reproduced by QCD Monte Carlos such as HERWIG or PYTHIA, including parton showers and hadronization. Instead in the resolved case ($x_\gamma^{OBS} < 0.75$) there is a large discrepancy on the forward side: data show a considerably larger amount of energy. The same effect was observed by both experiments without a cut on x_γ^{OBS} for jets in the forward hemisphere [102, 118]. The effect can be attributed consistently to resolved photon events, since they are largely dominant for this configuration. A possible explanation is the occurrence of additional interactions between the proton and photon remnants, producing a soft underlying event or a superposition of soft and semi-hard multiple interactions. These phenomena should not happen in direct photon interactions where there is no photon remnant.

Multiple parton scattering has been studied in $p\bar{p}$ interactions in analyses of multi-jet events [119]. Recently a strong signal for it has been reported by the CDF Collaboration [120]. The jet shapes and the pedestal energy in $p\bar{p}$ interactions have also successfully been described by a multiple interaction model [121].

Multiple interaction models are currently implemented in many Monte Carlo programs like PYTHIA [121] and HERWIG [122], which cover both hadron-hadron and photon-hadron interactions and in PHOJET [123], which is specific to photoproduction. The simplest model in PYTHIA generates events starting from the LO QCD jet cross section, where the transverse momentum cutoff p_T^{min} is set quite low, in the range of 1 – 2 GeV. In this region the LO parton cross section diverges and becomes larger than the total non diffractive cross section σ_{nd} . The so-called unitarization procedure consists schematically in allowing more than one interaction per event, with mean $\langle n \rangle = \sigma_{parton}(p_T^{min})/\sigma_{nd}$

and fluctuations calculated from Poisson statistics. The resulting distributions are quite sensitive to $\langle n \rangle$, the cutoff p_T^{min} and the chosen parton densities. A similar model has recently been implemented in HERWIG. The PHOJET generator is intended to simulate at once all the components contributing to the total photoproduction cross section. It is based on the two component Dual Parton Model [124] and includes multiple soft and hard interactions on the basis of a unitarization scheme [125]. Due to this scheme the dependence on the p_T^{min} separating the soft and hard regions is rather weak. The soft part is described by soft pomeron phenomenology, with parameters tuned to $p\bar{p}$ and low energy γp interactions.

These models have been used by the H1 Collaboration in a detailed study of the properties of photoproduction events related to underlying multiple interactions [103]. The average level of E_T outside jets has been studied in dijet events as a function of x_γ^{OBS} . In this study the pseudorapidity difference $\Delta\eta$ between the two jets was required to be $\Delta\eta < 1.2$, to avoid a possible mismatch of the photon remnant as a hard jet. In Fig. 33 the average transverse energy density $\langle E_T \rangle / \Delta\eta \Delta\phi$ is shown as a function of x_γ^{OBS} . It is determined from the summed E_T in the central region of the γp collision ($-1 < \eta^* < 1$), excluding the energy contained in cones of radius 1.3 around the jet axes. The long-dashed line is the energy density found in minimum bias events, where of course x_γ^{OBS} is undefined. The energy density increases significantly going from the direct photon ($x_\gamma^{OBS} \approx 1$), where it is close to the level found in minimum bias events, to low x_γ^{OBS} events. The increase is much higher than what is expected from QCD Monte Carlos without multiple interactions like the PYTHIA dotted curve, and cannot be attributed to gluon radiation or fragmentation effects. Instead data can be described by models with interactions between the beam remnants as PHOJET or the PYTHIA dashed line.

This becomes more convincing when one looks at the energy-energy correlation with respect to the central region. The pseudorapidity correlation function $\Omega(\eta^*)$ is defined as:

$$\Omega(\eta^*) = \frac{1}{N_{ev}} \frac{\sum_{i=1}^{N_{ev}} (\langle E_{T,\eta^*=0} \rangle - E_{T,\eta^*=0,i}) (\langle E_{T,\eta^*} \rangle - E_{T,\eta^*,i})}{(E_T^2)_i} \quad (55)$$

H1 has measured this quantity with respect to $\eta^* = 0$, where the average transverse energy density is at the maximum, for a sample of high E_T events. The result is shown in Fig. 34: data show short range correlations around $\eta^* = 0$ and long range anticorrelations in the photon hemisphere, with a minimum at $\eta^* \approx -1.8$. From PYTHIA without multiple interactions one would expect stronger correlation and anticorrelation than data show. Adding multiple interactions the correlation is reduced in both signs and agreement with data greatly improves. The conclusion is that the addition of uncorrelated energy to the events results in the correct average E_T level in the underlying event (Fig. 33) and also gives the correct correlation strength (Fig. 34).

7.4 Unfolding the gluon density in the photon

The study of the underlying energy carried out by H1 has also been used to correct their measured jet energies by subtracting the pedestal. The applied correction is parametrized

as a function of η^{jet} and has size of $0.3 - 2.3$ GeV. From an analysis of dijet events with pedestal subtraction H1 [126] has unfolded LO parton variables, based on the PYTHIA Monte Carlo with multiple interactions included. This introduces some model dependence on the results. The data refer to 290 nb^{-1} tagged photoproduction data from the 1993 run: the final sample is not large, 292 events with selected two jets with $E_T^{jet} > 7$ GeV and $0 < \eta^{jet} < 2.5$. First it is demonstrated the need of a gluon component in the photon and then the gluon momentum distribution is unfolded at LO. The distribution of the selected events in the unfolded x_γ is shown in Fig. 35. The full histogram represents the expected contribution of quarks and antiquarks in the photon, the dashed histogram the direct photon contribution, which is added on top of the other. These two are simply obtained from a LO QCD calculation at the parton level, using GRV LO parton distributions for the proton and the photon. The proton parton distributions at the relevant momentum fraction are well known and do not weaken the resolving power on the photon parton distributions. Data are well above the histogram at low x_γ , which is right the region where the contribution of gluons in the photon is expected to be important. The need for a gluon component has been checked with a χ^2 test on this distribution, trying to fit data with LO QCD predictions without gluons in the photon. Only the sum of direct- γ and quark-antiquarks in γ has been considered and systematic corrections have been applied to both data and theoretical prediction in the sense to decrease the discrepancy. The resulting probability is found to be 0.1%. The unfolded gluon momentum distribution is shown in Fig. 36 divided by α_{em} . The average scale of the selected events is $\langle p_T^{jet} \rangle^2 = 75 \text{ GeV}^2$, where p_T^{jet} is used as factorization and renormalization scale for the QCD calculation. The resulting gluon distribution is compared to LO parametrizations of GRV-LO, LAC1 and LAC3. This latter is clearly excluded, in agreement with previous observations at HERA [118], TRISTAN [39, 40] and LEP [127]. The strong rise of LAC1 at low x is disfavoured, while GRV-LO is consistent with data. This measurement constituted the first extraction of a LO gluon density down to $x_\gamma = 0.04$.

7.5 Photon remnant

As we have seen, direct and resolved processes are physically distinct as is apparent from the x_γ^{OBS} distribution in dijet events, and enriched samples can be obtained by cutting on this distribution. Another possible separation criterion relies on the different topology of the events. Figures 37 and 38 show respectively a direct and a resolved event candidate as reconstructed in the ZEUS detector. In these pictures the z -axis (proton beam direction) points to the left. The direct candidate has no activity in the rear calorimeter, i.e. in the photon direction. Instead in the resolved candidate several particles are found to go in the photon direction. Both the events have in addition two high E_T jets. The activity in the rear direction is interpreted as coming from the fragmentation of the photon remnant, which is present only for a resolved photon.

The ZEUS Collaboration has studied the properties of the photon remnant in events with two hard jets with $E_T^{jet} > 6$ GeV and $\eta^{jet} < 1.6$ [128]. To look for a photon remnant jet, emerging with small p_T at small angles in the photon direction, the cone algorithm is

not well suited. The jet finding was instead carried out with the k_T -algorithm [129]. It is applied starting from single calorimeter cells, as if they were particles. The prescription of the algorithm is to evaluate for each pair of clusters (initially single cells) the quantity:

$$k_T^2 = 2 \min(E_i^2, E_j^2) (1 - \cos\theta_{ij}) \quad (56)$$

This is the transverse momentum of the lower energy cluster with respect to the higher energy cluster, for small angular separation θ_{ij} . The proton remnant (escaping detection in the forward direction) is considered as a pseudoparticle with infinite momentum along $+z$. After all the k_T^2 values have been calculated, the two clusters with minimum k_T^2 are merged and their four-momenta added to give the four-momentum of the new cluster. The procedure is iterated until for all pairs the resolution variable Y becomes larger than some threshold Y_{cut} . Here Y is defined as: $Y = k_T^2/(E_T^{tot})^2$, where E_T^{tot} is the total transverse energy in the event. In the ZEUS analysis this Y_{cut} value has been chosen to vary from event to event in order to find always three clusters (apart from the proton remnant), ordered according to their E_T^{jet} . After comparison between data and Monte Carlo events the photon remnant has been identified in most cases as the source of the third cluster, which appears typically in the photon fragmentation region. The final selection required for it a minimum energy $E_3 > 2$ GeV and pseudorapidity $\eta_3 < -1$. After these cuts the x_γ^{OBS} distribution is found to peak at low values as expected from resolved photon events. In Fig. 39/a-b the pseudorapidity and transverse momentum distributions are shown for the third cluster, identified as the photon remnant. A comparison with the standard QCD simulation by PYTHIA shows that data are shifted towards higher p_T and more central η values. The transverse momentum for the photon remnant is generated in PYTHIA with gaussian distribution $dN/dk_T^2 \sim e^{-k_T^2/k_0^2}$ with default $k_0 = 0.44$ GeV. This parameter determines the hardness of the k_T spectrum. A fit to the data requires a higher k_0 of 1.7 – 1.9 GeV. This observation agrees with studies suggesting that NLO contributions or fluctuations of the photon into $q\bar{q}$ pairs with high virtuality may lead to a photon remnant with sizeable transverse momentum with respect to the photon direction [130]. The properties of the jet from the photon remnant have been compared to those of the hard jets, assumed to originate from the hard parton scattering. Fig. 40/d shows the mean value of the particle transverse energy with respect to the cluster axis as a function of the cluster energy; Fig. 40/e shows the average values of the scalar sums of transverse and longitudinal particle energies with respect to the cluster axis as a function of the cluster energy. Particle quantities are measured from calorimetric islands, i.e. groups of adjacent calorimeter cells, and corrected to the hadron level by a complete detector simulation. Figure 40/f shows the energy flow as a function of the distance from the cluster axis, expressed as $1 - \cos \theta$. In all the plots the photon remnant and the hard jets exhibit the same hadronization properties. The average particle transverse energy with respect to the jet axis $\langle E_T^i \rangle$ is of the order of few hundred MeV and increases only weakly with the jet energy. The longitudinal component of the jet energy increases much faster than the transverse energy w.r.t the jet axis. Fig. 40/a-b-c compares the photon remnant distributions with expectations from PYTHIA; they are in good agreement after the tuning of the intrinsic k_T distribution of the photon remnant.

7.6 Open charm production

Heavy quark photoproduction has been the subject of many theoretical studies [131]. Recent NLO QCD calculations for the HERA energies have been published for both total and differential cross sections [132]. A large amount of data exist from fixed target experiments with center of mass energies below 20 – 30 GeV [133].

In leading order the dominant production mechanism is expected to be the direct photon-gluon fusion process $\gamma g \rightarrow Q\bar{Q}$, with $Q = c, b$, which is represented by the diagram in Fig. 21/a, where the fermion line is a heavy quark. This is mostly a photoproduction process, with a tail at high Q^2 which is not dominant. Charm production is much more abundant than beauty production; the predicted cross sections at HERA are about 1 μb for charm and about 10 nb for beauty. Monte Carlo studies show that the dominance of charm production still holds after the application of experimental tagging and selection criteria, that is why for the present analyses, with the achieved HERA luminosity, beauty production has not yet been considered. In LO QCD charm production can occur also in resolved photon interactions, mainly through the process $gg \rightarrow c\bar{c}$. The relative fraction of direct and resolved photon is very sensitive to the photon parton densities. For parametrizations not steeply rising at low x_γ , like GRV, the resolved contribution is of the order of 20%, while for LAC1 it is more than 50% of the total cross section. Another strong source of variations in the theoretical predictions is the value of the charm mass m_c , which is generally taken in the range 1.2 – 1.8 GeV. Variation of the mass in this range changes the total cross section by more than a factor of 2. Charm production is somewhat at the boundary of applicability of perturbative QCD, due to the relative smallness of the charm mass, which is here the relevant scale for the perturbative expansion. The renormalization scale is set to m_c and the factorization scales for proton and photon parton distributions are set to $2m_c$, according to [132]. Large variations occur by changing the scales. The large spread in the predictions justifies the interest in measuring the charm production at HERA, aiming to fix the input parameters of the calculation. The most interesting topic may be the determination of the gluon density in the proton, due to the predicted dominance of the direct photon production in the experimentally accessible region. In contrast to the measurements carried out from the scaling violations in DIS [33, 134], the gluon density enters directly at the leading order of QCD in charm production. Several possibilities to extract it have been investigated [135, 136].

HERA experiments have measured the charm production mainly through the reconstruction of the $D^*(2010)^\pm$ meson decays. The golden channel is $D^{*+} \rightarrow D^0\pi_s^+$, due to the very small mass difference between D^{*+} and D^0 , $\Delta M = 145.42$ MeV; the slow pion π_s^+ has only 40 MeV momentum in the D^* rest frame. This special kinematic constraint allows ΔM to be measured more accurately than the D^* mass itself [137]. The D^0 has been reconstructed in the channels $D^0 \rightarrow K^-\pi^+$ or $D^0 \rightarrow K^-\pi^+\pi^+\pi^-$. The charge conjugate decay chain from the D^{*-} is implicitly considered.

Results on the total cross section $\gamma p \rightarrow c\bar{c}X$ have been published by both ZEUS [138] and H1 [139]. H1 results come from 1994 data, amounting to 2.77 pb⁻¹ tagged

photoproduction data ($Q^2 < 0.01 \text{ GeV}^2$, $159 < W < 242 \text{ GeV}$) and 1.29 pb^{-1} untagged data ($Q^2 < 4 \text{ GeV}^2$, $95 < W < 268 \text{ GeV}$). The accepted kinematic region is $p_T(D^*) > 2.5 \text{ GeV}$ and $-1.5 < \hat{y}(D^*) < 1$, where $\hat{y}$ indicates the rapidity. The p_T cut depends on the minimum p_T needed to measure the tracks from the D^* decay. The rapidity cuts select a well understood region of the tracking detectors. No particle identification has been used yet; well measured tracks are simply combined to form invariant masses. These measurements are shown in Fig. 41 as a function of the average γp center of mass energy W , together with lower energy measurements from fixed target experiments [133]. The cross section rises by almost one order of magnitude compared to the energy range of fixed target experiments. The curves are NLO QCD calculations [132] with parton density sets MRS(G) [140] for the proton and GRV-HO for the photon. They limit the variation produced by a change of the renormalization scale μ in the range $m_c/2 < \mu < 2m_c$. The limited acceptance of the HERA experiments makes the measurement of the total charm cross section rather model dependent, because of the need to extrapolate from the accepted kinematic region. The extrapolated $\sigma_{\gamma p}$ increases by 75% if LAC1 photon parton densities are used instead of GRV-HO; it decreases by 35% if the MRS(A') proton parton densities are used instead of MRS(G). These uncertainties are included in the error bars. Data are not able to discriminate between different available gluon density parametrizations, even though they favour rising distributions at low x . The visible cross section is instead almost insensitive to the choice of the parton distributions and to the mixture of direct and resolved processes assumed in the Monte Carlo to calculate the efficiency. Then cross sections within the experimental cuts can be safely compared with theory in a model independent way.

Differential cross sections versus the transverse momentum or the (pseudo)rapidity of the D^* have been measured by both the experiments [139, 141]. ZEUS data come from 3 pb^{-1} of the 1994 run. Fig. 42 shows the differential cross section $d\sigma/dp_T$ for the observed $D^{*\pm}$. The theoretical curves are two very different NLO QCD calculations: the dotted and the dashed-dotted curve stem from an exact fixed-order NLO calculation including the charm mass [132]; the full curve is instead a NLO resummed calculation, where the charm mass is neglected in comparison to the c -quark transverse momentum [143, 144] (limit of large p_T/m_c). The latter approach has been pursued also by another group [145, 148] and is sometimes referred to as the massless approach. Within the limits of applicability of this approach the charm is considered an active flavour in both the proton and the photon structure. On the contrary in the massive approach charm is generated from light partons and is excluded from the initial state. Both the calculations take into account the probability for a charm quark to fragment to D^* : $\mathcal{P}(c \rightarrow D^{*+}) = 26.0 \pm 2.1\%$ [142]. The D^* spectrum is obtained from the calculated c -quark spectrum convoluting it with the Peterson fragmentation function [146], which apart from the normalization is:

$$f(z) \sim \left[z \left(1 - \frac{1}{z} - \frac{\epsilon_c}{1-z} \right)^2 \right]^{-1} \quad (57)$$

Here z is the fraction of the charm quark momentum taken by the D^* , and $\epsilon_c = 0.06$ is a free parameter which is fitted from experimental data [147]. The massive calculation

with default parameters gives the dash-dotted curve. It has the correct shape but the normalization is about half that of data. With an extreme choice of $m_c = 1.2$ GeV and renormalization scale equal to half the transverse mass the dotted curve is obtained. The effect of changing the charm mass in the range $1.2 - 1.8$ GeV gives only a $\pm 20\%$ variation inside the accepted region. Instead the resummed calculation with equal parameters gives the correct normalization. This agreement is somewhat unexpected at least in the lowest p_T region covered by the data, where the massive calculation should be definitely better. A possible explanation to this situation is suggested in [148]. Here it is argued that the ϵ_c parameter in the Peterson fragmentation function (57) varies sensibly depending on whether the fit to data is done using a LO or a NLO QCD calculation for the partonic piece of the cross section. Using their NLO resummed calculation the authors find the best fit for $\epsilon_c \simeq 0.015 - 0.02$ to be compared to the commonly used value 0.06, which is found with a LO calculation. This change would increase sizeably the D^* cross section within the experimental cuts, and would bring also the massive calculation closer to data. In Fig. 43 the differential cross section as a function of the D^* rapidity is shown, from the H1 analysis of untagged photoproduction data. Data are above the theoretical prediction of the massive calculation [132] in the forward region. Different curves show that the effect of changing the proton and photon structure functions is small. In particular using the LAC1 instead of the GRV(HO) set for the photon makes only a small variation.

7.7 Inelastic J/ψ production

Another relevant process to access the gluon density in the proton is inelastic J/ψ production. Here again the leading mechanism is thought to be a photon-gluon fusion, $\gamma g \rightarrow J/\psi g$, in the so-called Colour-Singlet Model [149], represented by the diagram in Fig. 44. The name is due to the assumption that the $c\bar{c}$ pair giving the J/ψ lies in a colour-singlet state. Extraction of the gluon density from this process has been the aim of analyses at fixed target experiments [150]. There, a discrepancy was found in the absolute normalization, with the data being higher than the predictions by a factor from 2 to 5. This was ascribed to missing higher order contributions (K-factor). Recently NLO QCD calculations have been performed [151, 152] and agreement with those data was obtained. HERA data have been published by H1 from an integrated luminosity of 2.7 pb^{-1} [73]. The selected decay mode was $J/\psi \rightarrow \mu^+ \mu^-$. The direct photon-gluon fusion process has to be separated by other processes with quite different characteristics, like diffractive production with proton dissociation and production via resolved photon [153]. They are best discriminated by measuring the inelasticity variable z , defined as:

$$z = \frac{p_\psi \cdot P}{q \cdot P} \quad (58)$$

where p_ψ , P , q are respectively the four-momenta of the J/ψ , the initial proton and the photon. This expression is evaluated from measured energy and momentum variables as:

$$z = \frac{(E - p_z)_\psi}{(E - p_z)_\gamma} = \frac{(E - p_z)_\psi}{\sum_h (E - p_z)_h} \quad (59)$$

with the sum extended to all the final state particles except the scattered electron. In the proton rest frame z would be simply the ratio of the J/ψ to the photon energy. $z \simeq 1$ in the elastic process $\gamma p \rightarrow J/\psi p$, since in that case almost all the photon energy is transferred to the J/ψ . $z \approx 1$ also for events where the proton diffractively dissociates. Experimentally if particles are detected from the proton breakup they are at very forward angles, with $p_z \simeq E$, thus contributing only a little to expression (59). On the other hand resolved photon production contributes at low z , due to the reduced energy that the photon brings into the hard subprocess. A clean sample of photon-gluon fusion events is selected in the range $0.45 < z < 0.9$ after detailed studies and Monte Carlo simulation of all the relevant processes. The cross section has been measured extrapolating to the low z range and is shown in Fig. 45/a. Data are compared to a NLO calculation in the colour singlet model [152] with different gluon density parametrizations. All the curves assume $m_c = 1.4$ GeV, $\Lambda_{\overline{MS}} = 300$ MeV and renormalization and factorization scales set to $\sqrt{2}m_c$. The agreement seems better for the distributions rising more steeply at low x , like MRS(G). Actually the NLO calculation is not reliable at high z and low p_T of the J/ψ . This is apparent from the differential cross section $d\sigma/dp_T^2$ in Fig. 46/a, where the theoretical curve bends over at $p_T^2 < 1$ GeV². A safe kinematic region to avoid theoretical problems is $z < 0.8$, $p_T^2 > 1$ GeV²: this corresponds to the requirement that the emitted gluon is hard. The cross section in this restricted region is shown in Fig. 45/b. Unfortunately the sensitivity to the input gluon distribution is decreased and all the curves agree with data. An exponential fit to $d\sigma/dp_T^2$ with an exponential shape $e^{-bp_T^2}$ gives a slope $b = 0.39 \pm 0.06 \pm 0.03$ GeV⁻², in agreement with the theoretical calculation which gives $b = 0.3$ GeV⁻² for $p_T^2 > 1$ GeV².

Data on inelastic J/ψ and ψ' production at the Tevatron [154] have shown a huge discrepancy with the predictions of the Colour Singlet Model. They can however be fitted assuming additional colour octet terms in the general formalism of Bodwin, Braaten and Lepage [155]. This is not a new model: the basic idea is that the $c\bar{c}$ pair may be either in a colour singlet or in a colour octet state before producing the J/ψ . In fact a colour octet state becomes a singlet simply by the emission of soft gluons. This non-perturbative step cannot in principle be neglected. The calculation needs phenomenological inputs which have to be fitted from data. To verify if HERA data are consistent with those observations, calculations have recently been performed to assess the effect of possible colour octet contributions at HERA [156, 157]. The prediction would be of a very steep increase of the production cross section for inelastic J/ψ at high z . In Fig. 46/b $d\sigma/dz$ as measured by H1 is compared to the prediction of NLO colour singlet alone and to LO colour octet fixing its parameters to the CDF data [154]. It is clear that HERA data exclude any large colour octet contribution.

8 Hard diffraction in photoproduction

Both ZEUS and H1 have reported the measurement of a large diffractive component in photoproduction, about 40% of the total γp cross section [55, 56], as discussed in section 5.

This is expected in view of the analogy of γp to hadron-hadron interactions. Diffractive processes are not limited to soft interactions. The first observations of diffraction in hard collisions at HERA have come from DIS measurements [158]. The experimental signature for diffractive events was the observation of a large rapidity gap around the proton beam direction. This is customarily specified by the variable η_{max} , defined as the pseudorapidity of the most forward energy deposit in the calorimeter with energy above 400 MeV. Diffractive event samples have been defined having $\eta_{max} < 1.5 - 2$, which means that no particles are seen in the detectors within a cone of $25^\circ - 15^\circ$ degrees around the proton beam direction. This cut selects mainly single photon dissociation events, where the initial proton is not broken up. Minor components are events where the proton dissociates to a low mass system which is not detected or non-diffractive events with unusual energy flow. About 10% of the DIS events were found to have the large rapidity gap signature. The dependence of the event rate on W as well as the approximate scaling observed in the DIS data indicated a diffractive process of leading twist. The diffractive structure function $F_2^{D(3)}$ [159, 160] and the cross section as a function of the mass of the diffractive system M_X [161] have then been measured. Hard diffractive events have also been observed in photoproduction [162]. Here events with high E_T jets and the large rapidity gap signature were found.

8.1 Jets and heavy flavours from photon diffractive dissociation

The picture of a hard diffractive event in photoproduction is shown in Fig. 47. No activity is seen in the forward calorimeter, although two hard jets are visible in the central region.

The interest in hard diffractive processes is motivated by the possibility of perturbative QCD calculations. This can help to understand the nature of the pomeron, considering it as a partonic system [163]. Ingelman and Schlein [164] gave a particle-like description of the pomeron taking inspiration from ISR pp data [165]. Their model was confirmed by the UA8 experiment [166], which observed jet production in $p\bar{p}$ diffractive interactions with a tagged leading proton.

Let us describe in some detail how the Ingelman-Schlein model is implemented. It assumes that the proton emits a pomeron: a colourless object with vacuum quantum numbers. The variable x_P is the fraction of the proton momentum taken by the pomeron. The square of the photon-pomeron center of mass energy is given by: $M_X^2 \simeq x_P y s$. The flux of pomerons from the proton is factorized in the cross section and its expression is derived from hadron-hadron data. It is a function of x_P and t , the momentum transfer from the proton. Different forms for the pomeron flux factor are currently used. The Donnachie-Landshoff form [167] is calculated in Regge theory with parameters fitted to hadronic data:

$$f_{P/p}(x_P, t) = \frac{9b_0^2}{4\pi^2} F_1(t)^2 x_P^{1-2\alpha(t)} \quad (60)$$

where $F_1(t)$ is the elastic form factor of the proton, $b_0 \simeq 1.8 \text{ GeV}^{-1}$ is the pomeron-quark coupling and $\alpha(t) = 1.08 + 0.25 t(\text{GeV}^2)$ is the pomeron trajectory. The systematic un-

certainty related to this choice is about 30%, from the comparison of different procedures to extract the flux factor.

In the Ingelman-Schlein model the pomeron is then assumed to be a source of partons which may interact with the photon in both direct and resolved processes, according to the pointlike or hadron-like behaviour of the photon. Parton densities of the pomeron $f_{i/\mathbb{P}}(\beta, \mu^2)$ are introduced in perfect analogy to the proton case, where β is the scaling variable, i.e. the fraction of the pomeron momentum carried by parton i , and μ is the energy scale at which the pomeron is probed. The partonic cross section is then calculated in LO QCD and factorization of these parton densities is assumed. If this would be the case they could be extracted independently of the experiment. Several forms for the pomeron structure have been suggested, the most extreme ones are the following:

- $\mathbb{P}$ entirely made of gluons, with a hard distribution:
 $\beta f_{g/\mathbb{P}}(\beta, \mu^2) = 6\beta(1 - \beta);$
- $\mathbb{P}$ entirely made of gluons, with a soft distribution:
 $\beta f_{g/\mathbb{P}}(\beta, \mu^2) = 6(1 - \beta)^5;$
- $\mathbb{P}$ entirely made of $q\bar{q}$ pairs (only two light flavours), with a hard distribution:
 $\beta f_{q/\mathbb{P}}(\beta, \mu^2) = \frac{6}{4}\beta(1 - \beta).$

The momentum sum for the pomeron is written as:

$$\Sigma_{\mathbb{P}}(\mu^2) \equiv \int_0^1 d\beta \sum_i \beta f_{i/\mathbb{P}}(\beta, \mu^2) \quad (61)$$

and in the Ingelman-Schlein model it is assumed $\Sigma_{\mathbb{P}} = 1$. This is however only a guess. Since the pomeron is not a real particle, the flux factor $f_{\mathbb{P}/p}$ and the momentum sum $\Sigma_{\mathbb{P}}$ may be not independent. In the following the dependence on μ^2 is neglected.

Jet cross sections in diffractive photoproduction have been measured by ZEUS [168] from 0.55 pb⁻¹ of untagged data. Data are corrected at the hadron level by detector simulation. Preselected events have a jet with $E_T^{jet} > 6$ GeV (at the calorimeter level) in the central region $-1 < \eta^{jet} < 1$. This corresponds to $E_T^{jet} > 8$ GeV at the hadron level. The invariant mass of the hadronic system is reconstructed as: $M_X = \sqrt{\sum_i E_i^2 - \sum_i \mathbf{p}_i^2}$, where the sum is extended to all the calorimeter cells. Fig. 48/a shows the correlation between M_X and η_{max} : it is apparent that there is a distinct class of events with low M_X that have low η_{max} , that is a large rapidity gap. The distribution of η_{max} for events with $M_X < 30$ GeV is shown in Fig. 48/b. The simulation of non-diffractive processes by the PYTHIA Monte Carlo is not able to describe the tail at low η_{max} . Instead the POMPYT Monte Carlo [169], based on the Ingelman-Schlein model [164], describes well the shape in this region. Fig. 48/c shows the M_X distribution after the cut $\eta_{max} < 1.8$ and Fig. 48/d the W distribution for the selected events. The flat W behaviour is in agreement with the expectations of POMPYT.

Figure 49 shows the differential jet cross section versus η^{jet} for the large rapidity gap events. Data include a contribution from double dissociation, where the proton diffractively dissociate to a hadronic system of mass $M_N \leq 4$ GeV which is not detected. The dominant errors are statistical, while the largest systematic error ($\approx 20\%$) is due to the uncertainty on the absolute energy scale of the calorimeter. LO QCD predictions obtained by Monte Carlo are superimposed. Large rapidity gaps may occur in normal non-diffractive events as fluctuations in the pseudorapidity distribution of the final state hadrons. They are however exponentially suppressed with increasing gap width. The size of the non-diffractive contribution has been estimated with PYTHIA using MRS(D-) parton distributions for the proton [184] and GRV(HO) for the photon. The result is considerably lower than data and differs in shape. Data are instead in good agreement with the expectations of POMPYT assuming a hard gluon density inside the pomeron, while a pomeron made of hard quarks gives the correct shape but too low a normalization. A soft gluon density gives inconsistent results on both shape and normalization. These data are however insensitive to an additional soft component in the pomeron, present together with the hard component.

The diffractive jet data are sensitive to both the quark and the gluon content in the pomeron. The recent HERA measurements of the diffractive structure function in DIS [159, 160] have provided information on the quark content. This appears to have both a hard and a soft component. Moreover these measurements do not favour a pomeron made only of quarks and antiquarks. If factorization of the pomeron parton densities holds, the pomeron structure would appear the same whether it is probed in DIS or in photoproduction. Therefore, assuming factorization, the gluon content of the pomeron can be studied combining DIS and γp jet data. For that purpose a pomeron composed of both hard gluon and quark distributions has been assumed, naming c_g and $c_q = 1 - c_g$ the relative gluon and quark fractions. Contributions from a possible soft parton component have been neglected, since the jet data are sensitive only to $\beta \geq 0.3$. The distribution of $d\sigma/d\eta^{jet}$ was corrected subtracting the non-diffractive and the double dissociation contributions. The first one was estimated with PYTHIA, which gives a good description of non-diffractive jet production in the central rapidity region. The latter was estimated from data to be $15 \pm 10\%$ and it has been assumed independent from η^{jet} according to the theoretical expectations. Then a χ^2 fit to the measured $d\sigma/d\eta^{jet}$ was carried out varying the gluon fraction c_g and leaving free the momentum sum (61) in POMPYT. The results are shown in Fig. 50 by the solid line. The shaded band gives the 1σ contour.

From the measurement of $F_2^{D(3)}(\beta, Q^2, x_P)$ in DIS we can find the quark contribution to the momentum sum, $\sum_{Pq}$, integrating over β and x_P :

$$\int_{x_{Pmin}}^{x_{Pmax}} dx_P \int_0^1 d\beta F_2^{D(3)}(\beta, Q^2, x_P) = k_f \cdot \Sigma_{Pq} \cdot I_{flux} \quad (62)$$

where I_{flux} is the integral of the pomeron flux factor over t and over the same region in x_P and k_f is a number depending on the assumed number of flavours (5/18 for two flavours, 2/9 for three flavours). The integral on the left hand side is performed using ZEUS data in the range $6.3 \cdot 10^{-4} < x_P < 10^{-2}$. The flux factor I_{flux} is calculated

using expression (60). The result is: $\Sigma_{\mathbb{P}q} = 0.32 \pm 0.05$ (0.40 ± 0.07) for two (three) flavours. The diffractive structure function $F_2^{D(3)}$ has been parametrized from ZEUS data in the β region $0.1 < \beta < 0.8$. Here the same form is assumed to hold in the whole range $0 < \beta < 1$. $F_2^{D(3)}$ is approximately independent of Q^2 in the range of the DIS measurements: $8 \text{ GeV}^2 < Q^2 < 100 \text{ GeV}^2$. Hence the dependence of $\Sigma_{\mathbb{P}q}$ on Q^2 is neglected. Moreover the Q^2 values are comparable to the values of $(E_T^{jet})^2$ of the selected jet events. Thus the DIS results are expressed as a constraint in the $\Sigma_{\mathbb{P}} - c_g$ plane of figure 50 (dot-dashed lines):

$$\Sigma_{\mathbb{P}} \cdot (1 - c_g) = \Sigma_{\mathbb{P}q} = 0.32 \text{ (0.40)} \quad \text{for 2 (3) flavours} \quad (63)$$

Combining the two results and considering all the systematic uncertainties one obtains: $0.4 < \Sigma_{\mathbb{P}} < 1.6$ and $0.3 < c_g < 0.8$. From this nothing can be safely concluded on the validity of a momentum sum rule for the pomeron. However, assuming the same pomeron flux factor in DIS and photoproduction, this determination of the gluon content of the pomeron is independent on the normalization and even on the validity of a momentum sum rule. From this analysis one concludes that between 30% and 80% of the momentum of the pomeron carried by partons is due to hard gluons.

Further information on the partonic structure of the pomeron can be obtained from the diffractive production of heavy flavours. The diffractive production of J/ψ has been discussed in section 6 because of the similarity with the light vector meson analyses. It illuminates the realm of hard diffraction, exhibiting a strong difference from light vector mesons, particularly in the steep dependence of the cross section on the center of mass energy. Clean data samples [73, 74] with good statistics have already been studied at HERA and successfully compared to calculations based on perturbative QCD [80]. However for J/ψ elastic production the theory retains some weakness related to long distance contributions in the cross section. Instead the diffractive production of open charm is in principle free from these uncertainties and recently has attracted much theoretical interest [170]. This process has been searched for by H1 [139]. They observed evidence of diffractive charm production by inspecting the η_{max} distribution, shown in Fig. 51 for selected D^* events. Here statistical subtraction of the background under the mass peak has been applied. The QCD Monte Carlo representing non-diffractive production is unable to reproduce the distribution, while the hard diffraction model implemented in the RAPGAP generator [171] reproduces well the shape when added to PYTHIA. H1 sets a lower limit on the diffractive cross section for $p_T(D^*) > 2.5 \text{ GeV}$, $-1.5 < \hat{y}(D^*) < 1$ and $\eta_{max} < 2$ in untagged events ($Q^2 < 4 \text{ GeV}^2$ and $0.1 < y < 0.8$) to: $\sigma(ep \rightarrow D^{*\pm}X) > 145 \text{ pb}$ at 90% confidence level. Comparing this limit to predictions of RAPGAP, a quark dominated pomeron is disfavoured. In fact, the predicted cross section for a pomeron made of hard gluons is $\approx 800 \text{ pb}$, while for a quark dominated pomeron it is only $\approx 30 \text{ pb}$.

8.2 Hard colour singlet exchange

Another kind of hard diffractive process leads to the appearance of large rapidity gaps between two high E_T jets. These events would result from the exchange of a colour singlet

propagator in the t -channel, as in the diagram of Fig. 52/a. The propagator could be an electroweak gauge boson or a strongly interacting object. The normal QCD jet production is instead described as a strong process with the exchange of a quark or a gluon propagator, as in Fig. 52/b. The colour charge of the propagator generates the colour connections between the hard jets. For this reason the pattern of soft gluon radiation is distributed over all the phase space, particularly in the central rapidity region between the two jets. Instead, for colour singlet exchange, the hard jets would be colour connected only to the beam remnants. In this case the central region would be depleted from particle production and could present the rapidity gap signature. This was first suggested by Bjorken [172], who also calculated the expected rate for this kind of events in $p\bar{p}$ interactions at the Tevatron ($\sqrt{s} = 1.8$ TeV). He estimated the contribution from the exchange of two gluons in a colour singlet state to be 10% of the cross section for single gluon exchange. Other calculations valid for high t have been published based on perturbative QCD [173, 174].

The topology of the relevant events is shown in Fig. 52/c. Two jets are shown in the η - ϕ plane, back-to-back in azimuth and separated by an interval $\Delta\eta$ in pseudorapidity. This is the pseudorapidity difference between the axes of the two jets. No particles are found between the jets in rapidity gap events.

The gap-fraction $f(\Delta\eta)$ is defined as the ratio of the number of dijet events having a gap $\Delta\eta$ to the total number of dijet events with jet-jet separation equal to $\Delta\eta$. It is expected to fall exponentially with increasing $\Delta\eta$ for non-diffractive processes. This follows assuming a constant pseudorapidity distribution of particles between the jets and is supported by analytic QCD calculations [174] and Monte Carlo results. Instead for colour singlet exchange the gap fraction is expected to be almost flat with $\Delta\eta$ [172, 174]. At large enough $\Delta\eta$ the colour-singlet exchange would then be dominating, as is shown in Fig. 52/d.

Allowing secondary interactions between the photon and proton remnants, the gap could be sometimes filled. A survival probability $\mathcal{P}$ has been defined in [172], such that the observed gap-fraction is the product of $\mathcal{P}$ and the gap probability at the parton level, which is a calculable quantity. Estimates of the survival probability for $p\bar{p}$ collisions at the Tevatron are in the range 5 – 30% [172, 175]. The same quantity at HERA could be higher due to the substitution of the $\bar{p}$ with the γ and the lower center of mass energy.

Both the Tevatron experiments D0 [176] and CDF [177] reported the observation of an excess of events with two hard jets separated by a rapidity gap, with respect to the expectations from normal QCD processes with colour exchange. The measured excess is about 1% for D0, 0.8% for CDF.

ZEUS published results based on 2.6 pb^{-1} of 1994 data [178], requiring two jets with $E_T^{jet} > 6 \text{ GeV}$, $\eta^{jet} < 2.5$ and small boost $|\bar{\eta}| = |\eta_1 + \eta_2|/2 < 0.75$. A cone algorithm with $R = 1$ was used and the distance between the two jets was required to be $|\Delta\eta| > 2$ to have non-overlapping cones in η . Gap events were found by inspecting the calorimeter pattern of energy, identifying particles by “islands” of neighbouring calorimeter cells with summed E_T above a threshold of 250 MeV. A gap event was defined as an event having no particles

between the two jets with $E_T > 300$ MeV (after correction of the calorimeter energies). The result is shown in Fig. 53, where the excess of gap events is evident in the last bin. The largest systematic uncertainty in data comes from the cut on the E_T of the island and is included in the error bars. Data have been fitted with a function $f(\Delta\eta) = ke^{\alpha\Delta\eta} + \beta$, with α and β free parameters and k a normalization fixed by the obvious condition $f(\Delta\eta) = 1$ at $\Delta\eta = 2$. The result is shown as the solid curve, and $\chi^2 = 1.2$ for two degrees of freedom. The fitted parameters are: $\alpha = -2.7 \pm 0.3(stat.) \pm 0.1(syst.)$, $\beta = 0.07 \pm 0.02(stat.)_{-0.02}^{+0.01}(syst.)$. The size of the excess has been also checked comparing data with the expectations from PYTHIA, simulating non-diffractive jet production. From this comparison the excess is found to be 7%, in agreement with the result of the fit. The actual number of events due to colour singlet exchange could be even higher than 7%, accounting for a survival probability for the gaps. The larger excess of gap events found at HERA in comparison to the Tevatron results could come from the same underlying dynamics, given different survival probabilities for gaps in the two environments. At HERA the contribution to the gap events from γ/Z^0 or $W^\pm$ exchange cannot account for the observed excess, since $\sigma^{EW}/\sigma^{QCD} < 7 \cdot 10^{-4}$ in this kinematic range. Instead data can be explained by a hard diffractive process based on the exchange of a colour singlet combination of gluons.

9 Outlook

In this paper we have reviewed the published HERA results on photoproduction. The understanding of the hadronic structure of the photon as well as the understanding of photon induced reactions has greatly improved in the last few years. HERA data have played a central role. This progress will continue in the next years. We will not summarize here the covered contents, but rather prefer to have a glimpse on the future prospects for selected topics.

Most of the HERA measurements will have significant improvements in the next years with the expected luminosity increase. The final HERA results presented here include data up to the 1994 run, with integrated luminosity of about 3 pb^{-1} . The achieved luminosity during 1995-96 runs is about 20 pb^{-1} and almost the same should be achieved during 1997. Future upgrade plans aim at an integrated luminosity exceeding 100 pb^{-1} per year usable by the experiments.

Hard photoproduction processes at HERA are complementary to the $e\gamma$ deep inelastic scattering, being directly sensitive to both the quark and the gluon component of the photon. Data on jet photoproduction are presently consistent with the expectations of perturbative QCD. Ongoing analyses are studying extended domains in E_T^{jet} and η^{jet} , with different jet algorithms. The most severe experimental limitation on jet measurements is the energy scale uncertainty of the calorimeters, which can however be improved to about 2 – 3% from the 5% quoted in the results shown here. With such improvement large statistic samples with high E_T jets will allow more precise QCD tests. The measurement of

high p_T inclusive charged particle spectra has been recently proposed as a valid alternative to have access to the parton distributions in the photon [99]. It has the advantage of being insensitive to the energy scale of the calorimeter, at the price of an uncertainty due to the fragmentation functions, needed to describe the transition from partons to hadrons. The estimated accuracy on the extraction of a NLO gluon density by this method is about 10%. In parallel to HERA, the knowledge of the parton distributions in the photon (particularly the quark component) will be improved by high luminosity data from LEP2. From it high precision measurements of F_2^γ are expected up to Q^2 of few hundred GeV^2 and minimum x_γ about 10^{-3} .

The heavy flavour studies at HERA are presently all limited by statistics. The comparison of open charm (D^*) data with the existing NLO QCD calculations has proved to be an interesting and intriguing benchmark. In particular the discrepancy of the exact massive NLO calculation with HERA data has to be clarified. It could be due to uncertainties of the charm fragmentation function or, if nothing else, it might reveal the importance of higher order contributions (NNLO), which are far from being calculated. Apart from the normalization of the cross section, it will be interesting to see if the reported excess of D^* data in the forward pseudorapidity region will be confirmed. At reasonably high p_T values a safe comparison of the NLO massive calculation with the calculation resumming the large logarithms of p_T/m_c (the “massless” approach) should also help to understand the situation. Open charm data could also be used for a direct extraction of a NLO gluon density in the proton when a large data sample ($\approx 100 \text{ pb}^{-1}$) will be available, as it has been proposed in [136]. Charm tagging capabilities will benefit from detector upgrades of the interaction region with the introduction of a silicon microvertex detector. This has already been installed in H1 and is currently being developed in ZEUS.

Elastic vector meson production at HERA is being studied with larger statistics while varying the involved energy scales (Q^2 , t). The early results suggested the picture of a hard production mechanism, when a hard scale is present in the interaction, be it a high mass (as the J/ψ mass) or high Q^2 or t . Recent fixed target data on ρ production at high Q^2 make difficult to draw safely this conclusion for light vector mesons. Detailed studies varying the scales will possibly shed some light on the transition from a non-perturbative description of the pomeron (the soft pomeron), to the hard perturbative pomeron. Hard diffraction data from HERA (in which the final state has jets or heavy flavour particles) are presently indicating that the gluon content of the diffractive exchange is substantial. Many different models are appearing on the market and are being tested, trying to unveil the nature of the hard pomeron.

In conclusion, the study of γp interactions at HERA has yielded a lot of results. Several detector upgrades have already been performed (or are being done), which will result in improved purities of the selected samples as well as a wider kinematic coverage. Adding to this the expected much larger statistics, there is a bright future for photoproduction physics at HERA.

Acknowledgements

This work has been supported by an European Community fellowship. It is a pleasure to thank M. Arneodo, R. Brugnera, J. Dainton and Y. Yamazaki for useful discussions. I am specially grateful to M. Cacciari, A. Caldwell and S. Bhadra for a critical reading of the manuscript and many useful comments.

<i>process</i>	<i>cross section (μb)</i>						<i>full error (μb)</i>	
$\sigma(\gamma p \rightarrow XY), \textit{DD}$	20 $\pm$ 20 (assumed)						—	
$\sigma(\gamma p \rightarrow Xp), \textit{GD}$	23.4	$\pm$	2.6	$\pm$	4.3	$\pm$	10.2	11.3
$\sigma(\gamma p \rightarrow VY), \textit{PD}$	8.7	$\pm$	1.5	$\pm$	1.5	$\pm$	3.0	3.6
$\sigma(\gamma p \rightarrow Vp), \textit{EL}$	17.1	$\pm$	1.6	$\pm$	3.7	$\pm$	1.4	4.3
$\textit{EL} + \textit{GD} + \textit{PD} + \textit{DD}$	69.2	$\pm$	3.4	$\pm$	8.8	$\pm$	9.3	13.2
$\textit{ND}$	96.1	$\pm$	3.5	$\pm$	14.7	$\pm$	9.6	17.9
$\textit{Total}$	165.3	$\pm$	2.3	$\pm$	10.9	$\pm$	1.3	11.2

Table 1: Total and partial γp cross sections as measured by H1 [55]. The contribution of the double dissociation is assumed in the range: $0 < \sigma_{DD} < 40 \mu\text{b}$. The first error is statistical, the second one is systematic, and the third error is the systematic uncertainty due to the assumption on σ_{DD} . The full error is obtained as the quadratic sum of all of these.

<i>Reaction</i>	<i>Cross Sections (μb)</i>			
	Data	CKMT	SaS	GLM
$\sigma(\gamma p \rightarrow Vp), EL$	17 ± 4	17	16	17
$\sigma(\gamma p \rightarrow Xp), GD$	26 ± 5	25	13	18
$\sigma(\gamma p \rightarrow VY), PD$	9 ± 2	7	10	15
$\sigma(\gamma p \rightarrow XY), DD$	15	15	13	15

Table 2: Comparison of diffractive cross section calculations [59, 60, 61] with the H1 measurements [55]. The data are given for a fixed value $\sigma_{DD} = 15 \mu\text{b}$.

reaction	reference	$\langle W \rangle$ [GeV]	b [GeV $^{-2}$]	$ t $ -range [GeV 2]
$\gamma p \rightarrow \rho^0 p$	[66]	70	$10.4 \pm 0.6 \pm 1.1$	< 0.15
$\gamma p \rightarrow \rho^0 p$	[68]	70	$9.8 \pm 0.8 \pm 1.1$	$0.073 - 0.4$
$\gamma p \rightarrow \rho^0 p$	[67]	55	$10.9 \pm 2.4 \pm 1.1$	$0.025 - 0.25$
$\gamma p \rightarrow \omega p$	[69]	80	$10.0 \pm 1.2 \pm 1.3$	< 0.6
$\gamma p \rightarrow \phi p$	[70]	70	$7.3 \pm 1.0 \pm 0.8$	$0.1 - 0.5$

Table 3: Summary of the determinations of the b slope for elastic light vector meson photoproduction at HERA. The values of b have been obtained from a fit of the differential cross section of the form $\frac{d\sigma}{d|t|} = A \cdot e^{-b|t|}$ in the given t range.

Figure 1: The kinematics of a single-tag inclusive $\gamma\gamma$ event.

Figure 2: Quark-Parton Model (box) contribution to the photon structure function.

Figure 3: Recent data on $F_2^\gamma(x, Q^2)$ from TRISTAN [18, 19] and LEP [20, 22] compared to the LO fits to all previous data of LAC [27] and GRV [31]. Compilation from [179].

Figure 4: Q^2 evolution of F_2^γ averaged over $0.3 < x < 0.8$ (from [180]). The lines are predictions of the FKP model [24] with different phenomenological values of the cutoff parameter p_t^0 : 0.1 (dotted), 0.5 (solid) and 1.0 GeV (dashed). The VDM contribution is represented by the dot-dashed line.

Figure 5: Parametrizations of the u -quark distribution in the photon at LO [27, 31, 29, 37] and NLO [31, 29, 35], from [179]. The NLO results are given in the $\overline{\text{MS}}$ scheme.

Figure 6: Parametrizations of the gluon distribution in the photon at LO [27, 31, 29, 37] and NLO [31, 29, 35], from [179].

Figure 7: Typical leading order diagrams contributing to jet production in two-photon exchange processes at e^+e^- colliders: (a) direct photon; (b) single-resolved photon; (c) double-resolved photon

Figure 8: Inclusive (a) jet and (b) two-jet cross sections as a function of the jet transverse momentum for the central pseudorapidity region $|\eta^{jet}| < 0.7$ from [39]. The contribution of the direct process only is represented by the dashed line. The other curves are predictions including direct and resolved processes, from different LO parametrizations [26, 27, 181]. The expectation from the DG parametrization excluding the contribution of gluons from the photon is also shown.

Figure 9: Kinematics of the semi-inclusive electron-proton scattering $ep \rightarrow eX$.

Figure 10: Schematic view of the central part of the ZEUS detector.

Figure 11: Schematic view of the central part of the H1 detector.

Figure 12: Integrated luminosity delivered by HERA as a function of the date of the year in the period 1992-1995.

Figure 13: Representative diagrams for the different classes of photoproduction processes: (a) elastic vector meson production $\gamma p \rightarrow Vp$; (b) diffractive photon dissociation $\gamma p \rightarrow Xp$; (c) diffractive vector meson production with proton dissociation $\gamma p \rightarrow VY$; (d) double diffractive dissociation $\gamma p \rightarrow XY$; (e) non-diffractive inelastic scattering $\gamma p \rightarrow H$.

Figure 14: Total photoproduction cross section measurements as function of the γp centre of mass energy $W_{\gamma p}$. Data are shown together with parametrizations which did not include HERA measurements: the solid curve is DL [51] with default pomeron intercept $\alpha_P(0) = 1.08$, while the dotted one is DL with $\alpha_P(0) = 1.11$ (which is obtained including in the fit the CDF result [46]); the dashed curve is ALLM [57].

Figure 15: Differential cross section $d\sigma/d|t|$ for elastic ρ^0 photoproduction, $\gamma p \rightarrow \rho^0 p$, at $\langle W \rangle = 73$ GeV, as obtained by ZEUS through direct measurement of the scattered proton. The line is the exponential fit described in the text.

Figure 16: Exponential slope parameter b as a function of E_γ , the photon energy in the rest frame of the proton. The curve is a prediction based on pomeron exchange [60].

Figure 17: Elastic vector meson photoproduction cross sections for ρ^0 , ω , ϕ , J/ψ as function of the γp center of mass energy. For comparison the total photoproduction cross section measurements are shown in the upper part of the plot. The data points at $W \geq 40$ GeV are HERA measurements, the lower energy points come from fixed target experiments. The dashed curves are expectations from the soft pomeron model [62], arbitrarily normalized at fixed target points in the elastic cross sections.

ZEUS 1994

Figure 18: The elastic J/ψ photoproduction cross section as a function of the γp center of mass energy W . In (a) the ZEUS data alone are fitted to a dependence W^δ with $\delta = 0.92$; the dashed line shows the prediction of a soft pomeron model [62] in which $\delta \approx 0.22$. In (b) HERA data are shown together with results from fixed target experiments. The full line is the result of a perturbative QCD calculation [80] using MRSA' proton parton distributions, the dotted and the dash-dotted lines are results of two pomeron models [78, 79].

Figure 19: Diagram representing elastic J/ψ production according to QCD-inspired models with the exchange of a gluon ladder.

Figure 20: The differential cross section $d\sigma/d|t|$ for the elastic process $\gamma p \rightarrow J/\psi p$ as measured by ZEUS in the kinematic range $40 < W < 140 \text{ GeV}$. The result of the exponential fit in the range $|t| < 1 \text{ GeV}^2$ is shown as the solid line.

Figure 21: Examples of LO QCD (a) direct and (b) resolved photon processes.

Figure 22: Inclusive transverse momentum distributions of charged particles in photoproduction events at $\langle W \rangle = 180 \text{ GeV}$ averaged over the pseudorapidity interval $-1.2 < \eta < 1.4$. Solid lines indicate fits of equation (49) to the data in the region of $p_T < 1.2 \text{ GeV}$. The dotted line shows a power law formula (50) fitted to the non-diffractive data for $p_T > 1.2 \text{ GeV}$. The diffractive data are scaled down by two orders of magnitude.

Figure 23: Inverse slope of the exponential fit (49) as a function of the center of mass energy $\sqrt{s}$ for ZEUS γp data and hadron-hadron data from fixed target [182], ISR [183] and UA1 [96]. The ZEUS non-diffractive point is given at the γp c.m.s. energy, while the diffractive points are plotted at the energies corresponding to the mean value of the invariant mass $\langle M_X \rangle$ of the dissociated photon system. The dashed line is a parabola in $\log(s)$ and was fitted to all the hadron-hadron points to indicate the trend of the data.

Figure 24: Transverse momentum spectra of charged particles in different experiments: ZEUS and H1 photoproduction data are compared to data from OMEGA [95], UA1 [96], and CDF [97].

Figure 25: Differential ep cross section $d\sigma/dE_T^{jet}$ for inclusive jet production integrated over two η^{jet} ranges: $-1 < \eta^{jet} < 2$ and $-1 < \eta^{jet} < 1$ (scaled down by an order of magnitude). The kinematic range is $Q^2 < 4 \text{ GeV}^2$ and $0.2 < y < 0.85$. The shaded bands give the uncertainty due to the energy scale of the jets. The superimposed lines are results of a NLO QCD calculation [106] using MRS(D-) [184] proton parton distributions and two different photon parton distributions: GRV-HO [31] (solid line) and GS-HO [29] (dashed line).

Figure 26: Differential ep cross section $d\sigma/d\eta^{\text{jet}}$ for inclusive jet production integrated over E_T^{jet} from three different thresholds ($E_T > 8, 11$ and 17 GeV) in the kinematic range $Q^2 < 4 \text{ GeV}^2$ and $0.2 < y < 0.85$. The shaded bands give the uncertainty due to the energy scale of the jets. The superimposed lines are NLO QCD results as in the previous figure.

Figure 27: Jet width measurements as function of the scaled jet transverse energy $2E_T^{\text{jet}}/\sqrt{s}$ from H1 [103] and UA1 [110]. H1 data are normalized to the ep center of mass energy. Γ is defined as the full width at half maximum above the pedestal energy determined from the E_T azimuthal profile distribution around the jet axis in H1 data and from the pseudorapidity profile in UA1 data. The line represents a $1/E_t^{\text{jet}}$ fit to the H1 data.

Figure 28: The uncorrected x_{γ}^{OBS} distribution (indicated with x_{γ}^{cal}) from events with at least two reconstructed jets measured by ZEUS. The solid and dashed histograms represent respectively the expectations from PYTHIA and HERWIG Monte Carlo and have been normalized to fit the direct peak in the data. The shaded histogram shows the direct contribution to the HERWIG distribution.

Figure 29: Differential ep cross section $d\sigma/d\bar{\eta}$ for inclusive dijet production in the direct photon sample defined by the cut $x_\gamma^{\text{OBS}} > 0.75$, as measured by ZEUS. Jets are required to have $E_T^{\text{jet}} > 6$ GeV and $|\Delta\eta| < 0.5$ and the events to have $Q^2 < 4$ GeV² and $0.2 < y < 0.8$. The shaded band gives the uncertainty due to the energy scale of the jets. The data are compared to analytic LO QCD calculations [113] using the GS2 photon parton distributions [29] and different sets for the proton: GRV-LO [32], CTEQ2M [186], MRSA [140] and MRSD0' [185].

Figure 30: Differential ep cross section $d\sigma/d\bar{\eta}$ for inclusive dijet production in the resolved photon sample defined by the cut $x_\gamma^{\text{OBS}} < 0.75$, as measured by ZEUS. Jets are required to have $E_T^{\text{j}et} > 6$ GeV and $|\Delta\eta| < 0.5$ and the events to have $Q^2 < 4$ GeV² and $0.2 < y < 0.8$. The shaded band gives the uncertainty due to the energy scale of the jets. The curves are LO QCD calculations using the MRSA [140] parton distribution set for the proton and different sets for the photon: LAC1-LAC3 [27], GS2 [29], GRV [31] and DG [26].

Figure 31: Differential ep cross sections $d\sigma/d|\cos\theta^*|$ for dijet production in direct and resolved photoproduction as measured by ZEUS, normalized to unity at $|\cos\theta^*| = 0$. Events are selected with $M_{jj} > 23$ GeV, $E_T^{jet} > 6$ GeV, $\bar{\eta} < 0.5$, $Q^2 < 4$ GeV² and $0.2 < y < 0.8$. Data are compared to LO and partial NLO QCD calculations [116].

Figure 32: Uncorrected transverse energy flow $1/N dE_T/d\delta\eta$ around the jet axis, for cells within one radian in ϕ of the jet axis for (a) direct and (b) resolved photon events, from the ZEUS analysis in [88]. The solid and dashed lines represent respectively the distribution from PYTHIA and HERWIG.

Figure 33: Average transverse energy density (per unit area in the $\eta - \phi$ space) in the central region $|\eta^*| < 1$ outside the two jets with the highest E_T^{jet} as a function of x_γ . The inner error bars are statistical, the outer ones result from the quadratic sum of statistical and systematic errors. The long-dashed line indicates the energy density measured in minimum bias events. The histograms show the expectations of different QCD generators with interactions of the beam remnants (full=PHOJET, short-dashed=PYTHIA), and without them (dotted=PYTHIA).

Figure 34: Energy-energy correlation with respect to $\eta^* = 0$ as a function of η^* for a high E_T event sample [103]. The dashed (dotted) histogram represents the prediction of the QCD generator PYTHIA with (without) interactions of the beam remnants.

Figure 35: Distribution of the unfolded x_γ from a two-jet event sample [126]. Only the statistical errors are shown. The histograms are PYTHIA Monte Carlo calculations showing the contribution of quarks from the resolved photon (solid) and of direct photon events (dashed).

Figure 36: The gluon momentum distribution of the photon divided by the fine structure constant α as obtained in the LO analysis of H1 [126] at a scale $\langle p_T^{jet} \rangle^2 = 75 \text{ GeV}^2$, compared to LO parametrizations: GRV (full) [31], LAC1 (dashed) and LAC3 (dotted) [27].

Figure 37: Direct photoproduction of jets as seen in the ZEUS detector: the figure on the left is a longitudinal section of the detector, in which the electron beam comes from the left and the proton beam from the right. Two central jets are visible, balancing each other in p_T . The upper right picture is a transverse view of the same event and the lower right figure is a lego-plot showing the transverse energy deposited in the calorimeter in bins of $\eta - \phi$.

Figure 38: Resolved photoproduction of jets as seen in the ZEUS detector, with the same meaning as in the previous figure. On the left plot the photon remnant (going to the right) is visible.

ZEUS 1993

Figure 39: Corrected distributions of the third cluster in photoproduction events with two other jets with $E_T^{jet} > 6$ GeV and $\eta^{jet} < 1.6$ as measured by ZEUS [128]: (a) pseudorapidity; (b) transverse momentum. The histograms are expectations from PYTHIA Monte Carlo: the full line is the default version, the dotted line is obtained with a higher intrinsic transverse momentum (k_t) for the partons in the photon, as explained in the text.

ZEUS 1993

Figure 40: Fragmentation properties of the photon remnant compared to those of the hard jets in selected resolved photon events measured by ZEUS [128] and to the expectations of PYTHIA Monte Carlo: (a) and (d) show the mean value of $\langle E_T^i \rangle$, the average energy transverse to the cluster axis per particle, as a function of the cluster energy; (b) and (e) show the average values of the total transverse ($\sum_i E_T^i$) and total longitudinal ($\sum_i E_L^i$) energy; (c) and (f) show the energy flow around the cluster axis.

Figure 41: Total charm photoproduction cross section as a function of $W_{\gamma p}$: measurements from ZEUS, H1 and previous fixed target experiments are shown. The error bars give the statistical and systematic errors added in quadrature, including the uncertainty in the extrapolation. The lines are predictions of a NLO QCD calculation [132] showing the effect of changing the renormalization scale from $\mu = 0.5 m_c$ (upper curve) to $\mu = 2 m_c$ (lower curve). The parton densities used in the calculation are MRSG for the proton and GRV-HO for the photon.

Figure 42: The differential ep cross section $d\sigma/dp_T^{D^*}$ for D^* photoproduction in the kinematic range $Q^2 < 4 \text{ GeV}^2$ and $115 < W < 280 \text{ GeV}$ integrated over the D^* pseudorapidity range $-1.5 < \eta^{D^*} < 1.0$. NLO QCD predictions are shown: the dot-dashed curve is the result of the massive calculation of [132] using MRSG and GRV-HO parton densities for the proton and photon respectively, $m_c = 1.5 \text{ GeV}$, renormalization scale $\mu_R = m_T$ and fragmentation parameter $\epsilon_c = 0.06$; the dotted curve is the same but with $\mu_R = 0.5 m_T$ and $m_c = 1.2 \text{ GeV}$; the full curve comes from the resummed calculation in [144] with the same parameters as the dot-dashed curve except the proton parton densities CTEQ4M [187].

Figure 43: Differential γp cross section for D^* photoproduction with respect to the D^* rapidity $\hat{y}$ integrated over $p_T(D^*) > 2.5 \text{ GeV}$. The histograms are predictions of a NLO QCD calculation [132] with $m_c = 1.5 \text{ GeV}$ and different parton densities: MRSG + GRV-HO (solid), MRSA' + GRV-HO (dashed), MRSG + LAC1 (dotted) for the proton and the photon respectively.

Figure 44: Photon-gluon fusion diagram for inelastic J/ψ production.

Figure 45: Total cross section for inelastic J/ψ photoproduction as a function of the γp center of mass energy with: (a) $z < 0.9$; (b) $z < 0.8$ and $p_T^2 > 1 \text{ GeV}^2$. The curves are NLO QCD calculations [152] with different input gluon distributions and contain a 15% correction accounting for ψ' background.

Figure 46: Differential γp cross sections for inelastic J/ψ production as measured by H1 in the energy range $30 < W < 150$ GeV: (a) with respect to $p_T^2(J/\psi)$, integrated over $z < 0.9$; (b) with respect to z , integrated over $p_T^2 > 1$ GeV^2 . The dashed curves are results of a NLO QCD calculation [152] in the Colour-Singlet Model, with GRV parton densities. The full line in (a) is a fit to the data at $p_T^2 \leq 5$ GeV^2 . The solid curve in (b) is the expected contribution of colour octet terms in a LO calculation [156].

Figure 47: Dijet photoproduction with a large rapidity gap around the proton direction as seen in the H1 detector. The left picture is a longitudinal section in which the proton beam comes from the right, the upper right picture is a transverse view and the lower right one is a lego-plot of the calorimeter energy pattern. This event has the scattered electron detected in the low-angle tagger, represented in the upper left corner.

Figure 48: (a) The scatter plot of M_X^{cal} versus η_{max}^{cal} for a jet event sample with $E_{T,cal}^{jet} > 6$ GeV and $-1 < \eta_{cal}^{jet} < 1$; (b) the distribution of η_{max}^{cal} for the events with $M_X^{cal} < 30$ GeV along with the predictions of PYTHIA (shaded area) and POMPYT with a hard gluon density in the pomeron (solid line). The predictions are normalised to the number of data events above and below $\eta_{max}^{cal} = 2.5$, respectively; (c) the distribution in M_X^{cal} for the events with $\eta_{max}^{cal} < 1.8$ together with the prediction of POMPYT with a hard gluon density in the pomeron (solid line) normalised to the number of data events; (d) the distribution in W^{cal} for the events with $\eta_{max}^{cal} < 1.8$ and the prediction of POMPYT as in (c).

Figure 49: Differential ep cross section $d\sigma/d\eta^{jet}(\eta_{max}^{had} < 1.8)$ for inclusive jet production with $E_T^{jet} > 8$ GeV in the kinematic region $Q^2 \leq 4$ GeV² and $0.2 < y < 0.85$. The measurements are not corrected for the contributions from non-diffractive processes and double dissociation. The shaded band displays the uncertainty due to the energy scale of the jets. The full curves are predictions of POMPYT for single diffractive jet production using the DL flux factor with different parametrizations of the pomeron parton densities (hard gluon, hard quark, soft gluon) and the GS-HO photon parton distributions. The expectation from non-diffractive processes is shown as the dashed line, which is obtained by PYTHIA with MRSD- and GRV-HO parton distributions for the proton and the photon respectively.

Figure 50: Constraints on the $\Sigma p - c_g$ plane, the momentum sum and the fraction of hard gluons in the pomeron. The solid line is the result of the χ^2 fit of the measured $d\sigma/d\eta^{jet}$ for the diffractive event sample with the predictions of POMPYT. The two dot-dashed curves are obtained from the measurement of the diffractive structure function in DIS [159], assuming two (lower) or three (upper) quark flavours. The shaded bands represent 1σ contours.

Figure 51: $\eta_{\max}$ distribution of D^* candidate events. The hatched histogram represents the contribution of non-diffractive processes, from PYTHIA, the solid histogram is the sum of the previous one with the contribution of diffractive processes from RAPGAP. The two components are respectively normalized to the number of events with $\eta_{\max} > 3$ and $\eta_{\max} < 2$.

Figure 52: Resolved photoproduction via (a) colour singlet exchange and (b) colour non-singlet exchange. The rapidity gap event morphology is shown in (c) where black dots represent final state hadrons and the boundary illustrates the limit of the ZEUS acceptance. Two jets of radius R are shown, which are back to back in azimuth and separated by a pseudorapidity interval $\Delta\eta$. An expectation for the behaviour of the gap fraction is shown in (d)(solid line). The non-singlet contribution is shown as the dotted line and the colour singlet contribution as the dashed line.

Figure 53: The gap-fraction as a function of the gap width from the ZEUS analysis of dijet events [178]. Data are compared to a fit to an exponential plus a constant.
